 - 4 Outcome measurement and feedback may provide early benefits by capitalizing on the surgical “Hawthorne effect,” but their impact may be limited if they are tied to coordinated efforts aimed at changing practice.
 - 5 With Qualified Clinical Data Registries, surgeons may be eligible for CMS pay-for-performance incentive payments by participating in ACS-NSQIP and other society-led registries.
 - 6 Although prophylactic strategies aimed at avoiding complications in the first place are obviously important, “rescuing” patients once a complication has occurred may be even more critical in reducing current variations in hospital mortality rates.
-

INTRODUCTION

Improving the quality of surgical care is a public health imperative. As many as 100,000 patients die every year undergoing surgery in the United States; an order of magnitude more experience serious complications.¹ Despite recent studies suggesting that surgery is becoming safer over time,² a large body of literature suggests that a large proportion of surgical morbidity and mortality may be avoidable. In its seminal 1999 report *To Err is Human*, the Institute of Medicine estimated that between 44,000 and 98,000 Americans die every year as a result of medical errors, at least half of whom are surgical patients.^{3,4} Evidence that morbidity and mortality vary widely across hospitals and surgeons further implies opportunities for improvement. In addition to variation among individual providers,^{5–7} surgical outcomes differ according to a number of provider attributes, including procedure volume, surgeon subspecialty training, and other factors.^{8–10}

In response, payers, policy makers, and professional organizations have launched a broad array of strategies aimed at improving surgical quality.¹¹ Some of these efforts, including the so-called Centers of Excellence (COE) programs, aim to direct surgical patients to hospitals or surgeons with the best results.¹² With pay-for-performance programs, payers are instead aiming to incentivize improvements at all hospitals, providing financial rewards (and penalties) to hospitals and/or surgeons meeting performance targets on both outcomes and process of care measures.¹³ And finally, surgical professional societies and state organizations are hoping to improve surgical quality through clinical outcome registries, performance feedback, and collaborative quality improvement activities.^{14–16}

Although hospitals and surgeons also engage in improvement activities at the local level, these three strategies – COE programs, pay for performance, and outcome feedback – represent the major, policy-level approaches to improving surgical quality at the present time. In this chapter, we review the relative strengths and weaknesses of each approach (Table 17-1). We close by reviewing new research on mechanisms underlying variation in surgical outcomes across hospitals and surgeons, and its implications for quality improvement in the future.

CENTERS OF EXCELLENCE

COE programs hope to identify hospitals and/or surgeons with the best results with selected procedures and direct as many patients as possible to these settings. In some instances, payers restrict insurance approval to narrow networks of approved providers. In others, they implement tiered health plans and benefits packages that give patients financial incentives (e.g., lower copays) to select higher-quality providers. Such programs generally make public comparative information about hospital and surgeon performance, hoping to further motivate patients to “shop for quality.”

Among the most prominent examples of active COE programs, Blue Cross Blue Shield Association identifies the so-called “Blue Distinction” centers for cancer care, cardiovascular surgery, organ transplantation, and bariatric surgery, based on periodic surveys of hospital performance on multiple different measures with each specialty area. The CMS until recently restricted bariatric surgery to hospitals designated as COE by either the American College of Surgeons (ACS) or the American Society of Metabolic and Bariatric Surgeons. Although led by employers and purchasers rather than payers, the Leapfrog Group is promoting “evidence-based hospital referral” for aortic valve replacement and complex cancer surgery, based on both procedure volume criteria and hospital mortality rates.¹⁷

Such strategies reflect the natural response of payers (and many patients) to data indicating variation in provider performance with surgery. Among other advantages, selective referral can often be implemented expediently and inexpensively, particularly when based on simple structural measures of quality (e.g., procedure volume). For many procedures, commonly used quality indicators can reliably identify groups of hospitals and surgeons with superior outcomes. For example, data readily obtained from administrative sources, including procedure volume and hospital mortality, not only describe past performance, but also forecast future performance with many procedures.¹⁸ A recent national study suggests the potential benefits of concentrating complex procedures in COEs. Based on national Medicare data, mortality with high-risk cancer surgery fell almost 20% between 1999 and 2008.² Approximately half of that mortality decline could be attributed to market concentration – more procedures being done in high-volume hospitals.

Table 17-1 Characteristics of Three Different Models for Reducing Variation and Improving Surgical Quality

	Centers of Excellence Programs	Pay for Performance	Surgeon-Led Quality Measurement and Improvement
Goal/mechanism	Steer patients to high-quality hospitals or surgeons	Payers implement financial incentives that reward hospitals and surgeons for better outcomes or other measures of performance	Improve care in all settings by providing feedback on surgical outcomes; hospitals and surgeons implement improvement efforts at local level
Examples	Leapfrog Group evidence-based hospital referral program Payers’ Centers of Excellence programs in cardiac and bariatric surgery	Hospital Value-Based Purchasing Program of the Center for Medicare and Medicaid Services (CMS) CMS’ Physician Value-Based Modifier Payments	National registries/improvement programs administered by Society of Thoracic Surgery and American College of Surgeons Insurer-funded collaboratives in Michigan and other states
Advantages	Inexpensive, expedient Traction with patients and payers	Can facilitate rapid improvements in many aspects of perioperative care	High degree of surgeon buy-in Robust registries are important tool in identifying best practices
Disadvantages	Highly polarizing (for surgeons) For most procedures, hard to reliably identify “best” hospitals and surgeons with existing data	Provides no insights on how to improve Though effective on process measures, little effect to date in improving outcomes	Expensive Difficult to scale

1 Despite their conceptual appeal and potential benefits, the results of many COE initiatives have been largely disappointing. For example, analyses by Mehrotra et al.¹⁹ found no evidence that the Blue Distinction Centers had better outcomes than nondesignated hospitals with spine surgery and total joint replacement. In another study examining the effects of CMS’ 2006 policy restricting bariatric surgery to COEs, Dimick et al.²⁰ found no evidence that COEs had better performance than non-COE, or that the CMS policy had improved outcomes overall. As a result of that study and others reaching similar conclusions,^{12,21} CMS decided to rescind its policy restricting bariatric surgery to COEs in 2013. These examples highlight problems with current approaches to assessing the comparative quality of hospitals and surgeons for COE purposes. These challenges include using administrative data to assess outcomes other than mortality, putting too much weight on hospital attributes and processes of care not tightly

linked to outcomes, and relying on self-reported data.²²

Measurement challenges aside, COE programs have other downsides. Strategies that displace patients from their usual site of care and regular physicians may interfere with coordination of care. They tend to be highly polarizing, dividing hospitals and surgeons into winners and losers. In alienating the latter, a price of COE programs may be lost opportunities for engaging physicians in other types of quality improvement efforts. And finally, such programs improve outcomes exclusively to the extent that they steer care away from poor performers. It provides no mechanism for helping non-COE hospitals and surgeons improve their outcomes.

PAY FOR PERFORMANCE

Another approach to improving surgical outcomes is to encourage hospitals and surgeons to provide higher-quality care with financial incentives. Both public and private payers have active pay-for-performance programs involving surgery. CMS has both a Value-Based Purchasing program aimed at hospitals and a more recent effort targeting physicians – the so-called Physician Value-Based Payment Modifier program.²³ Although such programs are moving toward specialty-specific outcome-based measures (as described later), pay-for-performance programs have until now focused on adherence to evidence-based practices related to perioperative care. For example, many private payers link hospital reimbursement to process measures established by the Surgical Care Improvement Project (SCIP),²⁴ including practices aimed at reducing rates of surgical site infection, postoperative cardiac events, venous thromboembolism, and ventilator-associated pneumonia.

Among their strengths, pay-for-performance initiatives aimed at improving compliance with specific processes of care are considerably less polarizing than selective referral. In theory, anyone can “win.” To the extent that surgeons can “play to the quiz,” process-based pay-for-performance programs have the potential to achieve rapid and significant improvements in many aspects in perioperative care. Studies in primary care suggest that pay-for-performance programs may be particularly effective in improving process compliance among poor performers and thus reducing overall variation.^{13,25} In surgery, evidence to date suggests similar improvements in compliance with SCIP measures.²⁶

2 Nonetheless, the extent to which improvements in evidence-based practice compliance translate to improvements in surgical outcomes remains uncertain. Studies to date have generally failed to demonstrate a strong correlation between provider performance with specific process measures and patient outcomes. For example, hospitals successful in examining at least 12 lymph nodes from the surgical specimens of patients undergoing colectomy for colon cancer, one popular measure, did not have better 5-year survival rates than those scoring worse on this quality indicator.²⁷ Even when hospital performance is measured across multiple, evidence-based practices related to a specific postoperative complication, process compliance is not well correlated with patient outcomes. In examining national data compiled by CMS’ Hospital Compare program, for example, Nicholas et al.²⁸ found that hospital compliance with the “bundles” of SCIP process measures related to surgical site infection and venous thromboembolism varied widely. Moreover, hospital compliance rates were not related to the incidence of those two postoperative complications.

A more recent study by Shih et al.²⁹ provides the most direct evaluation of the overall effects of surgical pay-for-performance programs. Focusing on coronary bypass surgery and total joint replacement, Medicare’s Premier Hospital Quality Incentive Demonstration (HQID) was intended to incentivize quality and quality improvement by increasing reimbursements to both top performing hospitals and those demonstrating the greatest degree of improvement over time.³⁰ While mortality and complication rates for cardiac and orthopedic patients decreased significantly over time in premier hospitals, improvements of similar magnitude were observed in nonparticipating hospitals.²⁹

3 Together, these studies do not invalidate the importance of timely antibiotics and other well-tested prophylactic measures against surgical complications. Rather, they underscore the complexity of surgical care and the limitations of focusing exclusively on a small number of discrete steps in managing a surgical patient. As we describe later, these studies also highlight that surgical outcomes also depend on aspects of care not traditionally addressed in pay-for-performance programs, like surgeons’ technical skill and their proficiency in managing complications after they have occurred.

OUTCOME FEEDBACK

In contrast to strategies led by payers and policy makers, surgeons and their professional organizations are focusing primarily on registry-based quality improvement programs.^{14,15,31} Their goal is to provide hospitals and surgeons with rigorous feedback about their outcomes relative to those of their peers. Some of these programs have centralized approaches to coordinating quality improvement activities, while others focus primarily on performance feedback, leaving improvement work at the local level.

The Scientific Registry of Transplant Recipients and the Adult Cardiac Surgery Database of the Society of Thoracic Surgeons were among the earliest and most recognized surgical outcome registries. The large majority of US hospitals involved in those two specialties now contribute to those databases.^{32,33} Originally developed by the Department of Veterans Affairs, the American College of Surgeons-National Surgical Quality Improvement Program (ACS-NSQIP) has become the largest outcome measurement platform for noncardiac surgery.^{14,34} Often supported by payers, state and regional collaborative improvement programs – based on either society-developed or “home-grown” outcome registries – have become increasingly popular.

This model of performance feedback and data-driven quality improvement has particular appeal among surgeons. As they represent the “bottom line” of success, outcome measures tend to be more meaningful to surgeons than process measures. When coupled with coordinated programs aimed at effecting practice change, registry-based improvement programs in surgery can be highly effective. In Michigan, for example, Blue Cross Blue Shield of Michigan has supported collaborative improvement programs across numerous surgical specialties.³⁵ Though not every initiative supported by the Michigan collaborative has been well studied, Michigan hospitals have substantially outperformed national benchmarks in cardiac, general, and bariatric surgery.¹⁶

4 Whether performance feedback alone improves outcomes remains less clear, however. Early studies support the existence of a surgical “Hawthorne effect” – that the process of measurement spurs improvement. For example, surgical morbidity rates at VA hospitals fell over 40% almost immediately after implementation of NSQIP in the early 1990s,⁶ before any systematic attempt to change practice across that system. Mortality rates with cardiac surgery have fallen dramatically over the past 20 years, coincident with national dissemination of the STS registry.³⁶ The extent to which secular trends toward declining surgical mortality can be attributed to society-led registries and reporting systems is uncertain, however. Using national Medicare data, we compared hospitals participating in ACS-NSQIP to a matched group of nonparticipating hospitals. Though hospitals in the former group had lower mortality rates at the time they enrolled in ACS-NSQIP, both groups improved at the same rate between 2006 and 2012.

Surgeon-led outcome registries and improvement programs have other limitations. Though this issue may fade in the future as electronic medical record data become more accessible, current programs rely on extensive and expensive manual data collection, which has limited their dissemination in most specialties. Outcome measures, particularly when assessed at the level of specific procedures, are often hindered by small sample sizes and can be too “noisy” to inform hospitals and surgeons of their true performance.³⁷ And finally, as currently implemented, most registry-based improvement programs have several important “blind spots,” such as addressing the appropriateness of surgical procedures, variation in surgeon technical skill, and management of patients with postoperative complications.

SUMMARY

5 Although this chapter has laid out some of the distinct features, advantages and disadvantages with each strategy, the field is fast evolving and the lines between COE programs, pay for performance, and outcome feedback are blurring over time. Connecting the first and third strategy, for example, the STS recently decided to allow hospitals participating in its registry program to publicly report their outcomes for COE programs and other purposes. In another example, CMS is expanding measurement options for physicians participating in its physician-based P4P program, allowing them to submit specialty-specific outcome data through the so-called Qualified Clinical Data Registries, including those administered by surgical societies.

Each of the three strategies would benefit from advances in quality measurement and improvement. COE programs in particular would benefit from measures that more reliably discriminate performance among individual hospitals and surgeons. As described elsewhere, individual measures of structure (including procedure volume), process of care, and outcomes have major limitations in reflecting provider-specific quality.³⁸ Composite quality measures, which empirically combine information from

several quality domains, appear very promising.^{39,40} As described by Dimick et al.⁴¹ such measures far surpass existing quality indicators in capturing true variation in provider performance. More importantly, empirically derived composite measures perform extremely well in forecasting a hospital's future outcomes, a key litmus test given the underlying goals of COE programs.

6 Although better statistical methods for assessing postoperative morbidity and mortality will help, it may be even more important that future initiatives target a broader range of performance domains. First, given that the use of surgical procedures varies as much as outcomes, practical measures of appropriateness – and the quality of surgeons' decisions to operate in the first place – are essential. Second, rather than focusing exclusively on aspects of perioperative care, quality measurement and improvement initiatives should target surgeons' operative proficiency. Recent research suggests that, at least for some procedures, the technical skill of the operating surgeon varies widely and may be the single most important predictor of patient outcomes after surgery.⁴² And finally, improving surgical quality will require reducing rates of the so-called “failure to rescue.” A growing body of research suggests that hospital mortality rates are explained less by their complication rates than by their case-fatality rates among patients with serious complications.^{43,44} Thus, ensuring timely recognition and effective management of complications once they have occurred may be even more important to the success of strategies aimed at reducing surgical mortality.

Chapter 18

Patient Safety

Darrell A. Campbell, Jr.

Key Points

- 1 Safety means “freedom from harm”; in the context of patient care, safety means freedom from harm associated with any medical action or treatment.
 - 2 Even though the system should be constructed to back up human fallibilities, it is instructive to recognize these fallibilities. This subject is hard to quantify, but a good list, developed in a family practice environment, reads as follows: hurry, distraction, lack of knowledge, premature closure of the diagnostic process, and inadequate aggressiveness in patient management.
 - 3 In the acute hospital setting, as opposed to the outpatient environment in family practice, safety problems typically involve poor handoffs, failures of teamwork, excess workload, and fatigue.
 - 4 Another approach to the implementation of safe practices is to educate and train physicians and nurses within the context of a team.
 - 5 The future of the patient safety movement depends on the development of an effective safety reporting mechanism.
-

IMPORTANT DEFINITIONS: SAFETY VERSUS QUALITY

1 The terms *quality* and *safety* have important bearings on any discussion of patient care. These are related subjects but have different meanings, and these differences should be underscored before any dialog about patient safety begins. Safety means “freedom from harm”; in the context of patient care, safety means freedom from harm associated with any medical action or treatment. Quality is a more global term referring to a “degree of excellence.” It is theoretically possible for a hospital to be safe, but for quality to be average or poor. It is not possible for a hospital to be of high quality and unsafe. In this chapter, we focus primarily on the subject of patient safety, but admit that some aspects of the subject drift into the area of quality as well.

THE PROBLEM

By now, all are familiar with the report issued by the Institute of Medicine (IOM) in 2000 entitled *To Err Is Human*.¹ The report was an exhaustive review of the status of safety in our nation’s hospitals. The bottom line – which served as a “burning platform” for the patient safety movement – was the astonishing calculation that between 44,000 and 98,000 Americans died annually in hospitals as the result of preventable medical error. The report produced a flurry of outrage from consumer groups and denials and refutations from medical groups, but when the dust settled, what was left was the recognition, by all groups, that something was seriously wrong in our medical care delivery system.

Comparisons are often made between the safety of airline travel and medical care. One airline disaster every 2 or 3 years produces calls for new regulation, better airports, more frequent mechanical checks, and earlier retirement for pilots. But consider medical care. If even the lower number of preventable deaths extrapolated by the IOM report (44,000 annually) were seen as accurate, and one accepted that an average of 350 passengers were on board every major commercial aircraft flight, deaths from medical error would be equivalent to 63 separate midair collisions per year in the airline industry, or 5 per month. Imagine the public outcry this would produce, the laws that would be quickly passed, and the boon to train travel that would result. With these staggering numbers as a backdrop, the IOM asserted that “it would be irresponsible to expect anything less than a 50% reduction in errors over 5 years.” Sadly, 15 years later, only a modest improvement has been seen, and this is evident only in the most recent 3 years.² Why the tepid response? It is safe to say that the government and the medical

community have been slow to acknowledge, and even slower to respond to the safety imperative.

CULTURE

Fundamental improvements in patient safety rest on establishing a robust safety culture, in which caregivers view the safety of patients as their most important mission. Culture is defined as “how we do things around here.” That is, there is a certain level of acceptance, or complacency, for what goes on in a given hospital. Complacency is the result of two assumptions, which in the past have not been challenged. One assumption is that medical errors exist because “humans will always make mistakes.” While superficially true, this statement fails to acknowledge that modern human factors engineering strategies can militate against commonly encountered errors. A concrete example of how human factors engineering can be brought into play involves something as simple as a connector for medical tubing. If the connector is designed such that it is not physically possible to connect an O₂ line to a CO₂ valve, a potentially catastrophic mistake becomes impossible. More globally, work hour restrictions for medical trainees, which reduce fatigue, could be expected to result in fewer errors by exhausted and stressed doctors. To date, human factors engineering has not been brought into the delivery of medical care effectively. While humans will always be capable of making mistakes, the number of mistakes will be reduced if design is targeted to what we know about human fallibilities.

The second assumption accounting for complacency is the notion that a medical error is the result of poor individual performance rather than an imperfect system of care. If an individual made the error, in isolation, the only thing to do about it would be to fire the hapless caregiver, or immerse him or her in intensive remedial education. The problem with this approach is that it does not apply to the next hapless caregiver faced with the same situation. And so, since there is a high turnover in most medical environments, mistakes continue to happen, caregivers continue to be fired, and nothing really changes. This sequence has been ingrained in the medical culture, and is an important reason why the medical community has been slow to respond to the safety crisis.

SWISS CHEESE AND MEDICAL ERRORS

A popular paradigm in the medical safety area is the “Swiss cheese” model, introduced by James Reason (Fig. 18-1).³ This model is a visual representation of the multiple system layers that could prevent a medical error from occurring. A beam of light, representing a latent medical error, passes through a hole in the cheese, which represents system vulnerability. The latent error passing through the system via vulnerability will result in a medical error. If enough systems are set up with vulnerabilities, but in different locations, it becomes progressively harder for the latent error to get all the way through, and to become manifest clinically. The point here is that, while we recognize that both humans and systems of care have vulnerabilities, the prevention of error lies at the door of hospital leadership. Positive results come from the establishment of a strong safety culture, and the establishment of effectively redundant systems of error prevention. This concept is a major paradigm shift in the patient safety movement.

2 Even though the system should be constructed to back up human fallibilities, it is instructive to recognize these fallibilities because systems do not always work. This subject is hard to quantify, but a good list, developed in a family practice environment, reads as follows: hurry, distraction, lack of knowledge, premature closure of the diagnostic process, and inadequate aggressiveness in patient management.⁴ The first three issues are probably obvious, but premature closure of the diagnostic process is a problem needing emphasis. Humans often fall into this trap. We see issues as black and white in an attempt to make sense out of complex circumstances. Hurry, distraction, and lack of knowledge contribute. Relevant pieces of Swiss cheese, which could counteract this tendency, include electronic diagnosis and decision-making aids; an institutional policy fostering physician interactions, teamwork, and second opinions; and setting and adhering to reasonable workload standards.

3 Depending on the environment, other fallibilities are exposed. In the acute hospital setting, as opposed to the outpatient environment in family practice, safety problems typically involve poor handoffs, failures of teamwork, excess workload, and fatigue.⁵

But what about the concept of individual responsibility? One cannot show up for work with a careless attitude, engage in irresponsible actions, and expect to be held unaccountable for poor performance because of the emphasis on systems. This is a delicate balance for any health care system. The

underlying principle here is that most employees of a hospital wake up each morning wanting to do a good job, and to avoid mistakes, and hence (with exceptions) the general philosophy should be that a major improvement in safety will be at the level of system engineering rather than individual fallibility. When the onus of individual fallibility is lessened (not removed entirely), there then emerges a new sense of system responsibility, with increased willingness to identify system errors and to participate in safety enhancement as a group. This collaborative participation does not occur when one is worried about punitive consequences for reporting and the possibility of job loss.

LEADERSHIP AND POLICY

A robust safety culture is essential, but how does one change a culture? This is not done easily. There are two crucial elements, which, if effective, can change the culture direction positively. The first element is set by the example of hospital leadership. When the rank and file sees that the hospital CEO places patient safety at the top of the list and backs this priority up with funding, a lot of good things happen. When the CEO emphasizes a change in hospital policy, with an emphasis on safety, the change is reinforced. We introduced two policies that serve as examples to make this point. The first, the “full disclosure” policy, stipulated that employees were obligated (not just encouraged) to disclose fully to patients important errors made in rendering their care. Remarkably, this policy resulted in fewer malpractice claims against the system, but more importantly, it underscored for employees the institutional emphasis on openness and honesty.⁶ The second policy change implemented was the “speak up with safety concerns” policy, which stipulated that no caregiver could be punished for voicing a concern involving patient safety, regardless of feelings hurt or hierarchy violated. Again, this written policy clearly articulated a health system goal – that patient safety trumped all other considerations.

One manifestation of an improved safety culture is an increased error reporting rate. Clearly, the error reporting rate will not go up if there exists widespread fear of retribution for reporting. What is desired is an increased rate of error reporting, but a decreasing rate of events resulting in temporary or permanent harm. This pattern suggests that caregivers are vigilant, care about safety, and are reporting on “near misses.” The data from “near misses” represent a treasure chest of information that can be used to prevent actual mistakes. We have seen increased reporting in association with the purchase of a new electronic reporting format. Whether a change in culture or a change in reporting format is responsible for the increased level of reports is hard to say, but we believe that it is some combination of both (Fig. 18-2).

ASSESSING THE CULTURE

If one places priority on “improving” a safety culture, it is necessary that the “culture” can be measured. Validated culture surveys exist, which, if applied periodically in a hospital environment, give important insight into the success of safety culture initiatives. We use the Agency for Healthcare Research and Quality (AHRQ) safety culture instrument primarily and survey all caregivers at approximately 2-year intervals. We use the resulting information in three ways. First, we use the aggregate response to answer the question, “Are we improving the safety culture?” and, if not, “What are the areas that need to be addressed institutionally?” On our last survey, a clear sore point at our institution was difficulty with “handoffs,” that is, the transfer of information between caregivers and teams. We then developed a taskforce focused on fixing the problem, over both the short and long term. The long-term solution is an electronic one; the short-term solution is a paper-based handoff tool. This effort was a direct result of information gained from the safety culture survey.

Figure 18-1. Systems failures.

Figure 18-2. Overview of the reporting system.

A second way we use the safety culture survey data is to identify specific hospital units that are struggling with a dispirited or complacent attitude toward the safety effort. Such problems often result from poor nurse leadership, disruptive physicians, or a lack of perceived resources. Armed with information about the safety culture (or lack of it), the institution can implement a focused strategy customized to the problem. Figure 18-3 shows results from our survey arranged by individual nursing unit, demonstrating certain units in need of help with error reporting and, conversely, units where the culture is good and institutional resources are not needed. A third source of information derived from the survey comes from narrative comments entered by individual caregivers. This is a very rich source of information and, since it is anonymous, often draws a fine line under issues that are hard to talk about in any other forum. Issues of suspected physician impairment, abusive behavior, or lack of leadership skills are sometimes identified.

Two important questions regarding safety culture and our efforts to improve it remain. First, using the AHRQ tool, have we seen an aggregate improvement over the past two survey intervals? Many safety initiatives have been instituted over this period of time, and yet the aggregate culture data have not shown much change. We interpret this information to mean that much more work needs to be done, and that changing a culture is a hard thing to do, akin to changing direction of an aircraft carrier. Also, over the period of time we have been studying our culture, our institutional activity has gone up dramatically, the complexity of our patients has increased, and nursing turnover has been high. Under these circumstances, no change in the safety culture data might be viewed more optimistically.

A second question is, "Are there individual strategies we have used that influence the safety culture positively?" If so, we could use these strategies more broadly. The answer to this question is yes. Patient safety rounds have been an important strategy that has improved the safety culture. Over the course of the past several years, we have made safety rounds on over 200 occasions, at 2-week intervals. Safety rounds are carried out by leadership (chief medical officer, chief of nursing, CEO, etc.) and a pointed 45-minute discussion ensues with the unit caregivers, including nurses, aides, clerks, and transporters. The culture effects of this endeavor are profound. When caregivers believe that the leadership is willing to listen, takes safety very seriously, and will put resources behind the articulated concerns, an overall feeling of confidence and support of the safety effort follows. Figure 18-4 demonstrates that caregivers having participated in patient safety rounds viewed the patient safety environment much more positively than those who had not.⁷

But, is a positive safety culture actually associated with improved safety? The assumption is yes, but data were hard to come by until recently. In Michigan, a multihospital collaborative was initiated (the Keystone Project), the objective of which was to implement evidence-based practices known to decrease the incidence of bloodstream infections (BSIs).⁸ A total of 107 hospitals were involved, and caregivers responded to the Safety Attitudes Questionnaire (SAQ), similar to the AHRQ tool described previously. Results (incidence of BSIs) were correlated with answers to the SAQ. The results are seen in Figure 18-5.

There was an important association noted between the best results (percent reduction in BSIs) and the most positive answers to SAQ questions. This is only an association (and subject to the usual caveats about associations vs. cause and effect), but important nonetheless. These results support the underlying hypothesis that when leadership prioritizes safety and implements actions to support safety, caregivers reflect this in their answers to the SAQ and this is associated with improved patient safety.

Figure 18-3. Nonpunitive response to error.

THE EVIDENCE BASE FOR PATIENT SAFETY

As important as it is to lay a strong foundation in safety culture, the energy and enthusiasm of caregivers to provide safe patient care must be rooted in activities that have been found to be effective. Unfortunately, there does not exist at this point a large base of evidence in patient safety, largely because the field is relatively young. The World Health Organization (WHO) convened a group to carefully analyze existing studies and highlight effective strategies with an evidence base.⁹ These are listed in [Table 18-1](#). Comments about specific evidence-based actions follow.

With regard to the administration of perioperative beta-blockers to prevent postoperative myocardial ischemia, it is very clear that patients already on such medications must be given them postoperatively. However, an initial interest in beta-blocker administration for patients never having received them previously evaporated as the result of the POISE trial.¹⁰ This was an international randomized controlled trial focusing on this specific issue, and the result, after analyzing many thousands of patients, was that giving beta-blockers perioperatively to naive patients caused more harm than good. Specifically, treated patients developed more troublesome bradycardia and hypotension than controls, and this resulted in a higher incidence of stroke, obviating the potential benefit of the drug in preventing myocardial ischemia.

Figure 18-4. Comparison of 2007 Agency for Healthcare Research and Quality (AHRQ) data participants versus nonparticipants in patient safety rounds.

Figure 18-5. Teamwork climate across Michigan intensive care units.

Using maximum sterile barriers for central venous pressure (CVP) catheter insertion to prevent BSI may seem obvious, and the implementation of this protocol has resulted, in many studies, in a dramatic fall in the incidence of this complication. This strategy is complemented by the use of antibiotic-impregnated CVP catheter lines and the use of chlorhexidine in the daily maintenance of the insertion site. The use of ultrasound to help guide CVP catheter line insertion is clearly effective.

Prevention of the feared complication of ventilator-associated pneumonia is a very important consideration, since this development has a high fatality rate and is very expensive to treat. There is some evidence that the continuous aspiration of subglottic secretions is important. Our institution has been successful in decreasing the ventilator-associated pneumonia rate dramatically ([Fig. 18-6](#)) using the multipronged strategy described in [Table 18-2](#).

Table 18-1 Evidence-based Interventions for Safe Patient Care

- Appropriate use of prophylaxis to prevent venous thromboembolism
- Use of perioperative beta-blockers in appropriate patients to prevent perioperative morbidity and mortality
- Use of maximum sterile barriers while placing central intravenous catheters to prevent infections
- Asking that patients recall and restate what they have been told during the informed consent process
- Continuous aspiration of subglottic secretions to prevent ventilator-associated pneumonia
- Use of pressure-relieving bedding materials to prevent pressure ulcers
- Use of real-time ultrasound guidance during central line insertion to prevent complications
- Patient self-management for warfarin to achieve appropriate outpatient anticoagulation and prevent complications
- Appropriate provision of nutrition, with a particular emphasis on early enteral nutrition in critically ill and surgical patients
- Use of antibiotic-impregnated central venous catheters to prevent catheter-related infections

DEVELOPING CONSENSUS

Given the paucity of real evidence to achieve what we think of as safe patient care, and because there is an urgent need to act, another strategy has been to develop consensus guidelines. Although such guidelines are not based on randomized trials, there is value in getting the best and most experienced minds together to synthesize what all would agree to be best practices. Trials may come later to support or refute consensus.

A very influential group that develops consensus guidelines is the National Quality Forum (NQF), an organization of a wide variety of experts, consumers, government officials, and corporate directors. The NQF several years ago published its list of “30 Safe Practices” recommended for implementation. Because this chapter is oriented toward surgery, [Table 18-3](#) lists a selection of the 30 Safe Practices germane to the inpatient setting.

Consensus and Accreditation

The NQF works closely with the Joint Commission. When the NQF has reached consensus on a specific safety practice, this is often translated into a Joint Commission requirement for hospital accreditation, in this setting recognized as Joint Commission “patient safety goals.” These goals are more specific than consensus guidelines and have more “bite” to them, in that all hospitals need to fulfill these requirements in order to be accredited. For example, goal 7, “Reduce the risk of health care–associated infections,” stipulates, among other things, that hospitals have specific strategies in place to prevent surgical site infections (SSIs); that they provide regular feedback about SSI rates to caregivers, with follow-up for 30 days; that they discontinue the use of shaving as a method of preoperative hair removal; and so on. Goal 8, “Reduce the risk of patient harm resulting from falls,” stipulates that each hospital implement a specific falls reduction program.

Table 18-2 University of Michigan Protocol for Prevention of Ventilator-Associated Pneumonia (VAP)

- Hand washing/hand sanitizing
- Chlorhexidine oral rinse prior to intubation, then q12h on 0900–2100 schedule
- Oral care with swabs q2–3h
- Head of bed elevated 30–45 degrees on all patients at all times, unless medically contraindicated
- Extubate early – as soon as safely possible
- Turn off tube feedings when placing patients flat for turning or for procedures, unless small-bore feeding tube post pyloric
- Endotracheal tube tape changed every 48 h
- Minimal use of saline lavage
- Change ventilator tubing only when soiled
- Staff education and updates on VAP

Figure 18-6. Ventilator-associated pneumonia – University Hospital intensive care units.

Consensus, Accreditation, and Payment

The Centers for Medicare and Medicaid Services (CMS) has a lot to say about implementation of safety practices in that they pay a large fraction of the nation's health care bill. As it regards safety in surgery and hospital care, CMS has embarked on two important strategies. The first is the Surgical Care Improvement Project (SCIP), initiated in 2006, whose stated goal was to reduce the incidence of selected surgical complications by 25% by the year 2010. To do this, CMS produced several specific process measures required to be met by hospitals before receiving full payment for services. Private insurers soon followed suit. SCIP measures are listed in [Table 18-4](#). In contrast to the more broadly defined consensus guidelines, agreed-upon SCIP measures had a strong evidence base. Whether this effort will be translated into national improvement in results remains to be determined. The Joint Commission has also integrated certain SCIP measures into its evaluation requirements.

Table 18-3 National Quality Forum Safe Practices

- Create a culture of safety
 - Obtain explicit informed consent
 - ICU patients managed by critical care certified providers
 - Implement computerized physician order entry
 - Implement protocol for wrong side/site prevention
 - Evaluate for venous thromboembolism/implement prophylactic protocols
 - Develop facility-wide anticoagulation services
 - Adhere to effective measures for preventing bloodstream infections
 - Implement appropriate methods (antibiotic administration) for the prevention of surgical site infection
 - Evaluate each patient at admission for the risk of malnutrition
 - Develop effective hand sanitizing policies
- ICU, intensive care unit.

Results have been mixed. In some cases, a statistically meaningful relationship between adherence to selected measures (antibiotic timing, appropriate antibiotic) was associated with reduced rates of SSI.^{11,12} In contrast, a very large study involving over 60,000 patients within the Veterans Administration hospitals showed remarkable improvement in compliance with five SCIP measures, but without appreciable effect in reducing SSI, casting doubt on the value of this effort in the overall CMS strategy for improving patient safety.¹³

Another important strategy embarked upon by the CMS is known as “nonpayment for hospital-acquired conditions,” otherwise referred to as the “never event” policy. In this strategy, the CMS has determined that it will not reimburse for flagrant medical errors, such as wrong patient, wrong side, or wrong site surgery. Administrators and surgeons do not object to this policy as far as it goes. But great concern has been raised about other conditions on the “never event” list, such as venous thromboembolism (VTE) or patient falls. The controversy arises because in these cases there does not exist an evidence base that would allow a hospital to eliminate these events entirely. Perfectly appropriate VTE prophylaxis, for example, only reduces the incidence of postoperative VTE by 50%. This situation seems unfair, and the list of “never event” conditions is progressively growing longer. Whether this strategy will really improve quality and make patients safer remains to be proven.

Table 18-4 Surgical Care Improvement Program (SCIP) Process and Outcome

Measures

Infection (INF)
■ SCIP INF 1: Prophylactic antibiotic received within 1 h prior to surgical incision
■ SCIP INF 2: Prophylactic antibiotic selection for surgical patients
■ SCIP INF 3: Prophylactic antibiotics discontinued within 24 h after surgery end time (48 h for cardiac patients)
■ SCIP INF 4: Cardiac surgery patients with controlled 6 AM postoperative blood glucose
■ SCIP INF 6: Surgery patients with appropriate hair removal
■ SCIP INF 7: Colorectal surgery patients with immediate postoperative normothermia
Venous Thromboembolism (VTE)
■ SCIP VTE 1: Surgery patients with recommended venous thromboembolism prophylaxis ordered
■ SCIP VTE 2: Surgery patients who received appropriate venous thromboembolism prophylaxis without 24 h prior to surgery to 24 h after surgery

PATIENT SAFETY INDICATORS

The AHRQ is another national group, funded by the National Institutes of Health. Several years ago the AHRQ developed 21 patient safety indicators (PSIs), which are thought to reflect on an institution’s safety. These indicators are captured from a hospital’s coding system, using International Classification of Diseases-9 (ICD-9) codes after patient discharge. The PSIs are listed in Table 18-5. While useful information can be obtained from this system, a disadvantage is that the data are obtained from medical billing coders, and may not accurately reflect whether a complication was actually preventable. An example might be the PSI labeled “accidental puncture and laceration.” An enterotomy made during the course of a difficult dissection in an irradiated and multiply operated abdomen would fit into this category and be interpreted by nonsurgeons as an “accident.” The surgeon who was carefully dissecting under these circumstances would definitely not agree. Despite such limitations, the AHRQ PSIs will be publicly reported as a safety indicator by the government next year, and already form the basis of certain proprietary safety indices, such as those put forth by [HealthGrades.com](#) or the University Health System Consortium.

EFFORTS FROM THE WORLD HEALTH ORGANIZATION

Recognizing that patient safety should be a global imperative, the WHO, working with the Joint Commission, has embarked on an ambitious project to reduce the incidence of medical errors internationally. One effort, known as the “high 5’s” initiative, focuses on reducing five prevalent types of medical errors, over a 5-year period, in at least seven countries. The identified problem areas are: (a) managing concentrated injectable medicines, (b) ensuring medication accuracy at transitions of care, (c) improved communication during patient care handovers, (d) improved hand hygiene, and (e) performance of the correct procedure at the correct body site.

Table 18-5 Agency for Healthcare Research and Quality Patient Safety Indicators

1. Hospital-level patient safety indicators
 - Complications of anesthesia
 - Death in low-mortality DRGs
 - Decubitus ulcer
 - Failure to rescue
 - Foreign body left in during procedure
 - Iatrogenic pneumothorax
 - Selected infections due to medical care
 - Postoperative hip fracture
 - Postoperative hemorrhage or hematoma
 - Postoperative physiologic and metabolic derangements
 - Postoperative respiratory failure
 - Postoperative pulmonary embolism or deep vein thrombosis
 - Postoperative sepsis
 - Postoperative wound dehiscence in abdominopelvic surgical patients
 - Accidental puncture and laceration
 - Transfusion reaction
 - Birth trauma – injury to neonate
 - Obstetric trauma – vaginal delivery with instrument
 - Obstetric trauma – vaginal delivery without instrument
 - Obstetric trauma – cesarean delivery
2. Area-level patient safety indicators
 - Foreign body left in during procedure
 - Iatrogenic pneumothorax
 - Selected infections due to medical care
 - Postoperative wound dehiscence in abdominopelvic surgical patients
 - Accidental puncture and laceration
 - Transfusion reaction
 - Postoperative hemorrhage or hematoma

DRGs, diagnosis-related groups.

The WHO has focused on surgical care specifically through a separate effort referred to as the “Safe Surgery Saves Lives” campaign. One very tangible result of this effort is the Surgical Safety Checklist, shown in [Table 18-6](#).¹⁴ Now being tested in eight countries, the vision is that a standardized forum for intraoperative communication will be adopted internationally, much in the same way that the international aviation community has endorsed standardized flight checklists.

IMPLEMENTATION STRATEGIES

Establishing a safe culture is important, and emphasizing an evidence base and consensus guidelines is important, but ensuring implementation of what is known to be safe practice is critical and may be the most difficult of all safety strategies to accomplish. Several strategies have been helpful in our environment.

Adding Pharmacists to Rounds

Our medical center is a tertiary care referral center; the complexity of cases is high and always going higher. Transplants, complex oncologic problems, extracorporeal membrane oxygenation (ECMO) patients, and others with multisystem organ failure fill a large portion of our beds. The pharmacologic aspects of these cases are complex. Adding to the difficulty of managing such patients is the educational aspect of our enterprise, which guarantees a constant supply of new faces on rounds. To address these issues and to prevent errors, we have implemented a policy of adding a clinical pharmacist to each of our high-complexity services. The role of this individual is to suggest appropriate drugs, screen for allergies and incompatibilities, and monitor for important side effects. The program has been invaluable in improving patient safety at our institution and at others.¹⁵

Rapid Response Team

Mortality rates for in-hospital cardiac arrest have been high for decades, despite advances in cardiopulmonary resuscitation (CPR) techniques and cardiotropic medications. This is true particularly for “floor arrests,” those cases of arrest occurring outside of the intensive care unit (ICU). In our center, and in many others, analysis of CPR cases has led to frustration that insufficient attention had been paid to the patient’s condition in the hours prior to the arrest, at a time when interventions could conceivably have been very helpful.

One approach to this problem has been to develop a rapid response team (RRT), which is activated when certain physiologic parameters fall outside a specified range. Such parameters identified at our center are heart rate (<40 or >140 with new symptoms), respiratory rate (<8 or >36), blood

pressure (systolic <80 or >220, diastolic >110 with symptoms), and unexplained change in cognition or neurologic status of adult inpatients. A key feature of the RRT activation is that it is seen as mandatory for nursing; no judgment is required. If the parameters are exceeded, the RRT is activated. This relieves some of the anxieties experienced by nurses in the past about communication with physicians, particularly at odd hours. In our center, activation of the RRT results in the timely arrival of an experienced surgical ICU nurse and a respiratory therapist. If the conditions are found to warrant it, a hospitalist is called. This occurs in 15% of cases. There is controversy in the literature as to whether the RRT effort actually is effective.¹⁶ However, the concept has so much face validity that most hospitals have accepted it as an important strategy to improve a safety culture.

Table 18-6 World Health Organization Surgical Safety Checklist

Before Induction of Anesthesia	Before Skin Incision	Before Patient Leave Operating Room
Sign In	Time Out	Sign Out
■ Patient has confirmed: ■ Identity ■ Site ■ Procedure ■ Consent ■ Site marked/not applicable ■ Anesthesia safety check completed ■ Pulse oximeter on patient and functioning ■ Does patient have: ■ A known allergy? ■ No ■ Yes ■ Difficult airway/aspiration risk? ■ No ■ Yes ■ Risk of >500 mL blood loss (7 mL/kg in children)? ■ No ■ Yes, and adequate intravenous access and fluids planned	■ Confirm all team members have introduced themselves by name and role ■ Surgeon, anesthesia professional, and nurse verbally confirm ■ Patient ■ Site ■ Procedure ■ Anticipated critical events ■ Surgeon reviews: What are the critical or unexpected steps, operative duration, anticipated blood loss? ■ Anesthesia team reviews: Are there any patient-specific concerns? ■ Nursing team reviews: Has sterility (including indicator results) been confirmed? Are there equipment issues or any concerns? ■ Has antibiotic prophylaxis been given within the last 60 min? ■ Yes ■ Not applicable ■ Is essential imaging displayed? ■ Yes ■ Not applicable	■ Nurse verbally confirms with the team: ■ The name of the procedure recorded ■ That instrument, sponge, and needle counts are correct (or not applicable) ■ How the specimen is labeled (including patient name) ■ Whether there are any equipment problems to be addressed ■ Surgeon, anesthesia professional, and nurse review the key concerns for recovery and management of this patient

An interesting, and entirely unexpected, offshoot of the RRT has been the process, by the RRT team, of visiting nursing floors on a shift-by-shift basis prior to any RRT activation. This process lets the team become more familiar with patients who might subsequently warrant RRT activation. Visits often foster a discussion among caregivers and family as to whether any intervention is appropriate or warranted.

Crew Resource Management

4 Another approach to the implementation of safe practices is to educate and train physicians and nurses within the context of a team. The team is defined, goals are set, and individual responsibilities are assigned. The completion of tasks (or omission) is apparent to members of the team, which provides a fail-safe structure. There has been considerable interest in crew resource management in the area of medicine since it has been conclusively shown to add value to aviation cockpit training. Crew resource management is probably best applied in small, well-defined areas, with relatively consistent staffing patterns, such as an operating room. In one report, a perioperative crew resource management training program consisted of an e-learning module, the development of laminated checklists and pocket-sized cards, briefing scripts, a communication whiteboard, and a hands-on training program facilitated by experienced personnel. Even with focused effort at crew resource management, perioperative safety practice implementation was found to be less than perfect, but the field, at least in medicine, is in its infancy, and it will probably be an important part of safety strategies in the years to come.¹⁷

Developing Collaborative Groups of Hospitals

Under conditions where motivated hospitals get together to discuss safety, the result is often a more consistent implementation of safety practices and better results. The development of a collaborative group directed at safety and/or quality allows for comparative evaluation of quality and safety, and often results in a spirit of friendly competition, which improves the aggregate level of safety.

A prominent example of such collaboration was mentioned previously, the Michigan Hospital Association–sponsored Keystone Initiative. Here, evidence-based practice for the care of patients in the ICU was monitored and found to be low across the state. A protocol was adopted for over 100 ICU

groups, which included elevation of the head of the bed 30 degrees, ulcer prophylaxis, regular respiratory weaning trials, and a central line insertion protocol, with line maintenance involving chlorhexidine patches. When the latter protocol was implemented, a profound drop in the incidence of BSIs across the state was seen, and the estimated cost savings exceeded \$160 million.⁸

In a different example, 64 Michigan hospitals formed the Michigan Surgical Quality Collaborative. These hospitals convene at 3-month intervals and share information about identified “best practices” and correlation with surgical results. Hospitals with the fewest complications in a specific area discuss why they feel they have been successful. “Best practices” are then distributed in a network including through the internet and a hardcopy newsletter. Each hospital implements strategies it feels are appropriate for its situation. The result has been a sharp drop in the incidence of surgical complications. The results suggest that a collaborative quality organization, with regular and intensive sharing of data and best practices, is an essential vehicle for quality improvement.

PATIENT AND FAMILY INVOLVEMENT

One element of the patient safety movement that will become more important in the future is the involvement of the patient in various hospital safety strategies. A valuable source of information, and an important feedback mechanism, is lost when the patient, or family, is not a part of the care process. Two examples of the value of patient involvement involve hand washing and urgent care.

For hand washing, an effective hospital strategy prompts patients to ask physicians, “Have you washed your hands?” when they come into the patient’s room. Physicians frequently wear buttons in this effort, which say, “Ask me if I’ve washed my hands.” While it may seem trivial and somewhat demeaning to the physicians, the fact remains that the percentage of physicians and nurses washing their hands prior to patient contact remains far below 100%, and the prevalence of patient infection with *Clostridium difficile*, vancomycin-resistant *Enterococcus*, and other hospital-acquired infections remains high. In this context, patient involvement could be seen as a very important piece of Swiss cheese.

Another example of patient and family involvement in the care process is the concept of “family activation” of the RRT. Family members are often more aware of changes in a patient’s condition than nurses or doctors, for the obvious reason that they know the personality and traits of the patient in detail. “He wouldn’t complain about this unless it was really bad” is an important source of information from a wife. In the past, this clue to an evolving situation was sometimes lost on caregivers more focused on vital signs and urine output. In “family activation” of the RRT, family members are allowed to call a phone number activating the RRT if they feel that more attention is needed to a given situation. While it might seem that this would let loose a flood of such calls, in actuality, this has not been the case.

DEVELOPING A TAXONOMY FOR PATIENT SAFETY

Ultimately, comparative data on the safety of patient care in this country will be available to the public, much in the same way that the safety of retail products, medications, and automobiles is currently reported. For any reporting system to be valuable and fair, the definitions of safety events need to be refined and agreed upon. It is not possible to compare the safety of different hospitals if definitions used are not standardized. Many national organizations are working on this topic. The WHO has recently developed an “International Classification for Patient Safety” designed to “define, harmonize, and group patient safety concepts into an internationally agreed upon classification in a way that is conducive to learning and improve patient safety across systems.” This work, while difficult, is essential for the patient safety movement.¹⁸

PUBLIC REPORTING OF SAFETY DATA

5 We live in an age of transparency. The public wants – and deserves – information about the safety record of a given hospital. And yet, such information is hard to find. The future of the patient safety movement depends on the development of an effective safety reporting mechanism. This is because, in the absence of a large-scale database, information is not disseminated effectively, and one hospital may

easily make the same mistake as its sister hospital down the street. One major impediment to the development of a national safety database is the lack of a standardized taxonomy of patient safety events. This problem is being addressed, as was just described.

Public reporting has been initiated using both voluntary and mandatory designs. Two examples of successful voluntary reporting systems are the National Nosocomial Infection Survey, a branch of the Centers for Disease Control and Prevention, and the MEDMARX program of the U.S. Pharmacopeia. Mandatory safety reporting systems are often state initiated and provide various sanctions for hospitals known to be engaged in unsafe practices. This penalty provides a disincentive to report, however. Only a few states have successful mandatory reporting systems.

One very successful example of a voluntary reporting system, albeit in the field of aviation, is the Aviation Safety Reporting System. This system analyzes 30,000 reports annually. Its success has depended on these factors: the system is simple, it is safe (for the reporting pilots), and it provides value. The patient safety movement would do well to emulate this system. When it does, and the taxonomy is standardized, doctors, nurses, and administrators will be considerably more willing to make safety data available to the public.

Part Two **Surgical Practice**

SECTION A: TRAUMA

Chapter 19

Trauma and Trauma Care: General Considerations

Hasan B. Alam

Key Points

- 1 Injuries are the leading cause of death in young Americans, and account for 1 out of every 10 deaths in the world.
 - 2 Deaths due to penetrating trauma and motor vehicle collisions are decreasing whereas fall-related fatalities are rapidly rising reflecting the aging population.
 - 3 Establishment of trauma systems that use evidence-based triage and treatment protocols saves lives.
 - 4 Bleeding is the number 1 cause of preventable deaths.
 - 5 The vast majority of trauma-related deaths are within the first few hours (<6 hours) after sustaining injuries.
 - 6 Early hemorrhage control is the major priority along with balanced resuscitation using an appropriate ratio of blood products.
 - 7 Recent military conflicts have rapidly advanced trauma care in many domains, and these developments are now being transferred to the civilian trauma settings.
-

BURDEN OF DISEASE

1 Injuries and violence affect everyone, regardless of age, race, or economic status. More young Americans (under 46 years of age) die of injuries than any other cause.¹ According to the Centers for Disease Control and Prevention, National Center for Injury Prevention and Control, about a quarter of all the emergency department visits are due to injuries (27 million in 2013),² resulting in 3 million hospitalizations and nearly 193,000 deaths – 1 person every 3 minutes.³ As opposed to cancers, cardiovascular diseases, and strokes, injuries disproportionally strike people in the prime of their lives. In fact, 59% of all deaths among people of 1 to 44 years of age in the United States are due to injuries, which is more than all noncommunicable diseases and infectious diseases combined. [Figure 19-1](#) shows the top 10 causes of death in different age groups in the United States, whereas [Figure 19-2](#) highlights the unintentional causes. Young males are the highest risk groups, not due to any specific physiologic disposition, but due to the propensity to engage in high-risk activities. Similarly, factors that increase risk taking and impair judgment (e.g., alcohol, drugs, crime, conflicts) further exaggerate the chances to get injured.

Although striking, the death data do not tell the entire story. Millions of injured people survive, but they face lifelong mental, physical, and financial problems that add to the societal burden. The resultant economic toll on our society is staggering. In 2013, the total cost of injuries in the United States was estimated to be \$671 billion. The costs associated with fatal injuries was \$214 billion while nonfatal injuries accounted for over \$457 billion.⁴ This problem also has global dimensions. According to the World Health Organization, injuries kill more than 5 million people, which is nearly 1.7 times the number of fatalities that result from malaria, tuberculosis, and human immunodeficiency virus, combined.⁵

EVOLVING MECHANISMS OF INJURIES WITH CHANGING POPULATION DEMOGRAPHICS

2 Motor vehicle collisions (MVC), firearms, falls, cutting/piercing instruments, poisoning, and burns are

among the leading mechanisms (Table 19-1).⁶ Their relative positions on the list are evolving. Over the last decade, better roads, safer cars, more frequent use of seatbelts, and so forth have resulted in a decrease in MVC fatality despite a marked increase in the number of cars on the roads and overall miles driven (Fig. 19-3).⁷ Drug overdose, suicide, and prescription medication abuse on the other hand are on the rise. For example, the age-adjusted suicide rate in the United States was 24% higher in 2014 than in 1999, and increases were observed for both females and males in all age groups under 75 years of age.⁸ In fact, we are witnessing a 30-year peak in suicide rates in the United States. Falls are also rapidly becoming a major health care issue due to increasing age of the population.⁹ Currently, in the United States, 1 in 9 Americans is aged 65 or older, which by 2050 will increase to 1 in 5 (Fig. 19-4).¹⁰ The fall rates are already climbing (Fig. 19-5) and are expected to jump up even more dramatically over the next few decades. These patients also have many more co-morbid problems, and the various age-related anatomic, physiologic, and immunologic changes makes it especially challenging to take care of these patients.^{11,12} Violent crimes were near record high from the 1970s to 1990s, but have shown a steady decline in the recent years (Fig. 19-6). When considering 5- and 10-year trends, the total 2013 estimated violent crime rate was 12.3% below the 2009 level, and 14.5% below the 2004 level.¹³ Despite the focus by the media on violent crimes, by most measures, we are now witnessing one of the safest eras in the American history.

CHANGING PATTERNS OF DEATH

3, 4, 5 The classical trimodal distribution of trauma deaths was described by Trunkey¹⁴ in 1983, based upon the patterns of post-traumatic deaths in several counties of Northern California. In that report, nearly half of the deaths occurred within minutes after injury due to disruption of major blood vessels, devastating central nervous system (CNS) injuries or combination. The only practical solution for this group appears to be better prevention strategies, as these deaths often occurred before any medical care could be delivered. A smaller second peak, lasting a few hours, followed that first major peak in mortality (~30% of the deaths) where depending upon the mechanism of trauma, ongoing hemorrhage and CNS injuries played an almost equal role. This group has been the impetus for the development of better trauma delivery systems (emergency medical services, rapid transport mechanisms, and dedicated trauma centers) across the world. In fact, data strongly show that preventable mortality is significantly lower in geographical areas that have well-established trauma systems.^{15,16} The third peak was noted days to weeks after injury due to infections, multiple organ failure (MOF) and various late complications. In more contemporary studies, the trimodal distribution has evolved into essentially a bimodal distribution, where 61% of the deaths are immediate, 29% early, and only 10% are late.¹⁷ Compared with the classical description, the percentage of immediate deaths remained unchanged, and early deaths occurred much earlier (median 52 vs. 120 minutes). However, unlike the classic trimodal distribution, the late peak has markedly diminished, most likely due to significant improvements in surgical intensive care. Mortality rates for many of the reasons for late death are rapidly dropping with wider adoption of best care practices for managing critical care illnesses.¹⁸⁻²⁰ For example, due to more judicious resuscitation practices severe respiratory failure after trauma has become a fairly rare occurrence.²¹ Clearly, critical care is resource intensive and adds significantly to our health care costs, but it has “flattened” the third peak. In other words, not only the incidence of late complications has dropped, but our ability to “rescue” patients even if they develop the complications has markedly improved. Today, even in massively bleeding patients (without head injuries) mortality beyond the first 24 hours is only ~10%.²² Unfortunately, the area where we have failed to alter the mortality remains the period immediately following the injury, including the prehospital phase. The majority of these deaths are due to hemorrhage and/or traumatic brain injury (TBI).²³⁻²⁶ Of these two conditions, bleeding is clearly more treatable, which makes it the number one cause of *preventable* deaths. Despite numerous advances in trauma care, a recent multinational trial of more than 20,000 patients²⁷ once again demonstrated that the majority of deaths (even in developing and under developed countries) occur within a few hours after injuries, with <2.5% of the injured succumbing to MOF.

*Data obtained from the National Vital Statistics Reports, Vol 64 no 2, February 2016 (Table 18, pages 84–85). The causes are listed alphabetically and the four most frequent are highlighted.

6 Despite obvious differences in the mechanisms of injuries, hemorrhage and TBI remain the leading causes of death not only in civilian but also in combat trauma,²⁸ and effective treatment strategies have the potential to save many lives in the battlefield.²⁹ Traditionally, management of a bleeding patient focuses on the replacement of lost blood, along with standard cardiopulmonary resuscitative strategies. The type of fluid used for resuscitation has evolved since it was introduced nearly a century ago. Toward the end of World War I and during World War II, transfusion of whole blood was the primary approach in the treatment of military traumatic hemorrhage. However, after World War II, the separation of whole blood into its components became widely accepted and replaced the whole-blood transfusion for logistical and financial reasons. During the Vietnam War era, use of salt-based solutions (crystalloids) became popular. Over the next 3 decades we saw a major rise in the volume of salt-water administration in trauma patients. Although it is cheap, easy to store and administer, from the very start there were concerns about the suitability of crystalloid fluids as a substitute for the lost blood. Blood is a complex fluid that contains thousands of proteins, cells that carry oxygen to the tissues (red blood cells) and generate clot to stop bleeding (red blood cells and platelets), various clotting factors, buffers, enzymes, and hormones. As crystalloids lack all of these, their administration results in rapid dilution of cells, clotting factors, and proteins, which can worsen bleeding. Thus, aggressive crystalloid resuscitation, especially in the absence of early hemorrhage control, is impractical, inadequate, and potentially harmful in many circumstances.^{30–33} Not only it lacks any specific pro-survival properties, large volume crystalloid infusion can exacerbate bleeding and worsens cellular injury.³⁴ It should be emphasized that survival in these patients requires definitive control of bleeding, and most deaths today are caused by delays in controlling the source of bleeding, and not due to inadequate delivery of resuscitation fluids. These challenges are compounded in austere circumstances such as a battlefield, where 87% of deaths occur before patients reach a medical facility,²⁸ yet nearly a quarter of these injuries are considered potentially survivable (PS). Not surprisingly, the PS category is largely (91%) made up of hemorrhage-related deaths, with most being truncal (67%).²⁸ In the injured that live long enough to reach a medical facility, the percentage of PS deaths increases to 51%, with hemorrhage accounting for 80%.²⁹ Thus, novel therapies that could improve hemorrhage control, and keep the injured alive long enough to get to higher echelons of care, have the potential to make the biggest difference.

Fatalities and Fatality Rate per 100 Million Vehicle Miles Traveled by Year

Figure 19-5. Death rates from unintentional falls. The figure is a line chart showing that during 2000–2013, age-adjusted death rates from unintentional falls increased steadily for both men and women aged ≥ 65 years, with consistently higher rates observed among men. During this period, death rates from falls increased from 38.2 per 100,000 population in 2000 to 67.9 in 2013 among men and from 24.6 to 49.1 among women. From National Vital Statistics System mortality data. Available at <http://www.cdc.gov/nchs/deaths.htm>.

*Per 100,000, age-adjusted to the 2000 U.S. standard population.

Figure 19-6. Death Rates for Three Selected Causes of Injury – National Vital Statistics System, United States, 1979–2012. In 2012, a total of 41,502 drug poisoning deaths, 34,935 motor vehicle traffic deaths, and 33,563 firearm deaths occurred. The age-adjusted death rate for drug poisoning more than quadrupled from 3 per 100,000 in 1979 to 13.1 in 2012. In contrast, the age-adjusted rate dropped from 22.1 to 10.9 for motor vehicle traffic deaths and from 14.7 to 10.5 for firearm deaths during this period. The age-adjusted drug poisoning death rate exceeded the motor vehicle traffic death rate beginning in 2009. From CDC WONDER, compressed mortality file, underlying cause-of-death, available at <http://wonder.cdc.gov/mortsql.html>.

BIOMECHANICS OF INJURY

It is important to realize that at its most basic level injuries result from deformation of tissues that results in damage. In general, injuries can be categorized as penetrating (sharp objects or firearms) or blunt. There are clearly differences between these mechanisms that must be kept in mind while evaluating the patient. Penetrating trauma causes injury to the objects that are in the path of the foreign body, whereas blunt trauma causes damage either through crush or shear forces. The diagnostic and management approach is therefore very different.

Blunt trauma is best understood by applying the rules of kinetic energy transfer: $KE = (M \times V)/2$, where KE is kinetic energy, M is mass of the object, and V is velocity. Thus, a head on collision between two large sport utility vehicles ($\sim 6,000$ lb each) traveling at 65 mph can generate enormous amounts of forces. Various safety mechanisms in the modern vehicles direct this force away from the occupants of the vehicle, but the clinicians have a tendency to underappreciate the forces and the vectors involved in the collision. With frontal impact, the vehicle stops abruptly and the occupants continue to move

forward (if not belted) and either hit the steering wheel or slide under to hit their knees against the dashboard resulting in classic injury patterns (Fig. 19-7). In a rear impact, the kinetic injury generated depends upon the differences between the velocities of the two vehicles, and the occupant of the front vehicle abruptly accelerates forward resulting in cervical spine hyperextension (“whiplash”). Lateral impact imparts rotational forces and often results in significant protrusion of the passenger compartment. In addition to limb trauma, this can result in major torso (chest, abdomen, and pelvis) injuries. The rotational forces are also more likely to cause torsion injury where the mobile areas join relatively fixed structures (e.g., aortic laceration, cervical spinal ligamentous injuries). Rollover crashes are especially dangerous as the vehicle is impacted from various angles repeatedly during the process. The occupants of the vehicle are thrown around and may even be ejected from the vehicle. Ejection increases the chances of death by ~10 fold. Similarly, death of another occupant is considered a high-risk event, as it is a surrogate for the severity of impact or the complexity of the forces involved. The clinician also must specifically look for clinical evidence of energy transfer. For example, a “seat belt” sign across the abdomen must raise suspicion for energy transfer across the bowel, mesentery, pancreas, and the lumbar spine. Similarly, wedge fracture of L1 vertebra in this setting mandates ruling out a pancreatic injury as the pancreatic body drapes across the anterior aspect of L1. In fact, orthopedic injuries should be considered markers of kinetic energy transfer and make the clinicians proactively look for injuries to adjacent organs, nerves, vessels, and tendons (Table 19-2).

Penetrating trauma should broadly be considered in two categories based upon the mechanism. Sharp objects can cause lacerations or puncture wounds. Lacerations are relatively more straightforward as the structures in the depth of the wound can be examined and injuries to critical organs ruled out by careful inspection. Puncture wounds (or stabs), on the other hand, are challenging when it comes to ruling out occult injury to deeper structures. For example, stab wound to the neck can cause injuries to the airway, esophagus, blood vessels, thyroid gland, or intrathoracic organs. Similarly, stab wound to the abdomen, chest, flank, and so forth must be evaluated for potential intracavity vascular, solid organ or hollow viscus injuries. Historically, most of these patients used to get surgical explorations but now with better imaging techniques, carefully selected stable patients are often evaluated with advanced imaging studies and/or endoscopy, and managed nonoperatively.³⁵⁻³⁹ Clearly, there has been a recent increase in the use of computerized tomography (CT) scans in the evaluation of trauma patients,⁴⁰ and careful use of CT scan can reveal additional findings that may not be otherwise apparent.⁴¹ This, however, does not apply to stab wounds to the abdomen, where CT scan has been shown to add no value to the serial physical examinations and close observation.⁴² In this prospective study of 249 patients with stab wounds to the abdomen, the CT scan findings did not alter the clinical decision making. Forty-five patients (18.1%) underwent immediate laparotomy, 27 (10.8%) had superficial injuries allowing immediate discharge, and the remaining 177 (71.1%) underwent CT. Of these, 154 (87.0%) were successfully observed, with 20 (11.3%) requiring laparotomy, 2 (1.1%) thoracotomy, and 1 (0.6%) sternotomy. Of the 20 laparotomies, 16 (80.0%) were therapeutic. All patients who underwent therapeutic laparotomy did so based on their physical examination alone. The sensitivity and specificity of physical examination were 100% and 98.7%, respectively, while those of CT were 31.3% and 84.2%, respectively. Thus, even in this era of ubiquitous radiographic imaging, the burden is on the clinician to carefully evaluate the patient and make a clinical decision in the trauma bay. One reason CT scans can be misleading in stab wounds is because unlike the gunshot wounds where the track is easier to appreciate due to surrounding tissue injury and cavitation effect, the depth of stab wounds is notoriously difficult to determine on the CT scan. Often, the tissues come back together when the knife is withdrawn, making it difficult to determine the precise depth of penetration (often the knife has penetrated much deeper than the track that is visible on the scan). Thus, in stable patients, nonoperative management of penetrating abdominal trauma is not unreasonable, even if they have solid organ injuries,⁴³ but it is not a simple radiographic decision. In fact, it remains a *clinical* decision that should be made by an experienced trauma surgeon. These patients also require close observation, serial examinations, and monitoring of laboratory parameters for the next 12 to 24 hours. In settings where this is not possible (e.g., lack of 24/7 clinician availability), the safer option would be to explore the injured body cavity (either laparoscopic or open). Bullet wounds differ from stab wounds not only in the fact that the bullets impart significant kinetic energy depending upon their velocity and weight (Table 19-3) but can also cause “cavitation” effect. Cavitation occurs as tissues impacted by the bullet recoil and transmit the kinetic energy outward, creating a cavity due to the rapid acceleration and deceleration. This can injure organs/tissues that are adjacent to the bullet track even if not hit directly by the projectile. In addition to the kinetic energy, the actual area of injury is influenced by factors such

as profile of the bullet, tumble (spin and yaw), and fragmentation. A jacketed bullet does not deform much whereas a hollow point bullet fragments, spreads, and deforms (increasing the area of damage). Similarly, tumbling of the bullet increases the area of energy exchange and much larger zone of damage. Generally, low-velocity ($<1,200$ ft/s) or medium velocity (1,200 to 2,000 ft/s) firearms are more common in urban trauma, with high-velocity wounds seen typically in combat settings. The cavitation effect is significantly more pronounced in high-velocity injuries, and the kinetic energy differences translate into a much larger area of destruction, more devitalized tissues, and contamination (cavitation can pull in debris, clothes etc. into the wound). Injuries to multiple organs and structures, even in different body cavities, is possible with bullet wounds. In the operating room, it is important to set clear priorities, and to approach the injuries in a logical fashion. The first priority should be to control the hemorrhage quickly (clamps, catheters, packing, etc.), followed by a quick assessment to identify and treat other life-threatening injuries (pneumothorax, cardiac tamponade, etc.). This should be followed by control of contamination. Then the physiologic status of the patient should be assessed to determine whether definitive repair of all the injuries is feasible versus a “damage control approach” (Table 19-4) where only an abbreviated operation is done and patient brought back to the operating room later for additional interventions (after full resuscitation). While looking for injured organs in penetrating trauma, topography for anatomic proximity must be kept in mind. For example, penetrating injury to the carotid mandates that we exclude injury to adjacent organs such as jugular, trachea, esophagus, and the spine. Similarly, one hole in the bowel should prompt us to look for another hole (through and through injury) that may not be obvious, as well as examining other adjacent organs. For example, a bullet injury to the anterior wall of the stomach can easily pass through the posterior wall, through the pancreas, duodenum, vena cava, and the kidney, depending upon the trajectory. While trying to determine the trajectory, it is important to *not* assume that the subject was in a “normal” anatomical position (standing straight front facing with arms by his side) when shot. Typically, victims assume a variety of odd positions in an effort to avoid getting hit. In addition, bullets do not necessarily travel in a linear track and can bend and bounce off in atypical directions. Thus, gunshot wound to the chest can easily result in injuries not only in the chest (ipsilateral or contralateral), but also in the abdomen, pelvis, or the neck depending upon the course of the projectile. It is also wrong to notice two holes and assume that they represent a through and through gunshot wound. It is equally likely to be two separate gunshot wounds with both bullets still inside the body. As a general rule, the number of gunshot wounds and the number of retained bullets should add up to an even number; otherwise, you are either missing a hole or a bullet. Even in critically ill patients, quick x-rays of the chest/abdomen/pelvis, as a “bullet survey” can be very helpful before rushing to the operating room. This information can be critically important in planning the surgical approach, and in deciding which body cavity to tackle in what sequence.

Figure 19-7. A, B: Frontal deceleration impact.

Table 19-2 Patterns of Injury to the Head, Neck, Trunk, and Extremities Associated with Orthopedic Injuries

Diagnosed Injury	Associated Injury
Fracture – temporal, parietal bone	Epidural hematoma
Maxillofacial fracture	Cervical spine fracture
Sternal fracture	Cardiac contusion
First and second rib fracture	Descending thoracic aorta, intra-abdominal bleeding
Fractured scapula	Pulmonary contusion
Fractured ribs 8–12, right	Lacerated liver
Fractured ribs 8–12, left	Lacerated spleen
Fractured pelvis	Ruptured bladder, urethral transection
Fractured humerus	Radial nerve injury
Supracondylar humerus	Brachial artery injury fracture
Distal radius fracture	Median nerve compression
Supracondylar femur fracture	Popliteal artery thrombosis
Anterior dislocation shoulder	Axillary nerve injury
Posterior dislocation of hip	Sciatic nerve injury
Posterior dislocation of knee	Popliteal artery thrombosis

Table 19-3 Muzzle Velocity, Kinetic Weight of Projectile, and Approximate Maximum Kinetic Energy of Frequently Used Firearms

Description (Caliber)	Projectile Weight (g)	Muzzle Velocity (ft/s)	Kinetic Energy (ft/lb)
Pistols			
22 Short	29	1,000	72
38 Special	158	870	263
9-mm Luger	125	1,150	440
45	250	860	410
357 Magnum	158	1,430	695
44 Magnum	240	1,470	1,150
Rifles			
22 Long	40	1,150	150
56-mm M-16	55	3,200	1,248
30-30 Winchester	170	2,200	1,830

Table 19-4 List of Proposed Indications for Damage Control, Including Range of Values Reported in Various Articles

1. Core temperature <35°C (34°C–35°C)
2. pH <7.20 (7.10–7.30)
3. Base deficit >14
4. Systolic blood pressure persistently <80 mm Hg (70 mm Hg–90 mm Hg)
5. Blood transfusion >10 units packed red blood cells
6. Estimated blood loss >4 L
7. Operating room fluid replacement >10 L
8. Associated life-threatening injuries in second anatomical location
9. Vascular injuries in inaccessible locations
10. Inability to close the abdomen due to visceral edema
11. Clinical evidence of coagulopathy (nonsurgical bleeding)

FIELD TRIAGE DECISIONS AND EARLY PRIORITIES

Broadly speaking, the trauma patients can be divided into three categories: patients with (a) rapidly fatal injuries, (b) potentially fatal injuries, and (3) all others. A key component of effective prehospital triage is to properly place the injured into these categories based on the available data (mechanism of injury, age of the patient, co-morbid diseases, physiologic status, and injury patterns), and then make a rapid decision about what type of facility is the most appropriate for the patient. Committee on Trauma for the American College of Surgeons (ACS-COT) has developed detailed criteria for designating hospitals into different levels depending upon the resource availability, from the highest (level I) to the lowest (level IV). These criteria can easily be found in the Resources for Optimal Care of the Injured Patient – 2014.⁴⁴ Working with the Centers for Disease Control and Prevention, ACS-COT has also developed a guideline for the prehospital triage of the injured patients ([Algorithm 19-1](#)).⁴⁵ The document also contains very detailed guidelines about which patients should be transferred from lower-level to higher-level trauma centers ([Table 19-5](#)).⁴⁴ The key priorities during the prehospital phase are the ABCs of trauma care (airway, breathing, and circulation), with a major focus on hemorrhage control (direct compression, advanced hemostatic dressings, and tourniquets etc.). In patients that are in hemorrhagic shock but are breathing and maintaining adequate airway/oxygenation, intubation and mechanical ventilation should be avoided (especially for short prehospital times) as administration of sedating drugs and an increase in the intrathoracic pressure (due to positive pressure ventilation) further decreases the preload, which could precipitate an arrest. Judicious administration of crystalloid fluids is acceptable, but aggressive fluid resuscitation in the absence of hemorrhage control can worsen the outcomes. The proof of this concept in humans was published in the New England Journal of Medicine in 1994.³³ In that study, hypotensive patients with *penetrating injury* to the torso were randomized to routine fluid resuscitation, or resuscitation was delayed until bleeding had been surgically controlled. The results showed a survival advantage in the delayed resuscitation group (70% vs. 62%, $p = 0.04$). In fact, a systematic analysis of all the published data failed to find any support in favor of (or against) large volume crystalloid resuscitation in bleeding trauma patients.⁴⁶ As these studies had focused on young patients with penetrating trauma, the question remains whether these findings can be generalized to the blunt trauma population. The blunt trauma patients are typically older, may have a higher incidence of coronary and carotid stenosis, and about 20% to 30% have associated TBI (which can worsen due to hypotension). Furthermore, as opposed to penetrating trauma,

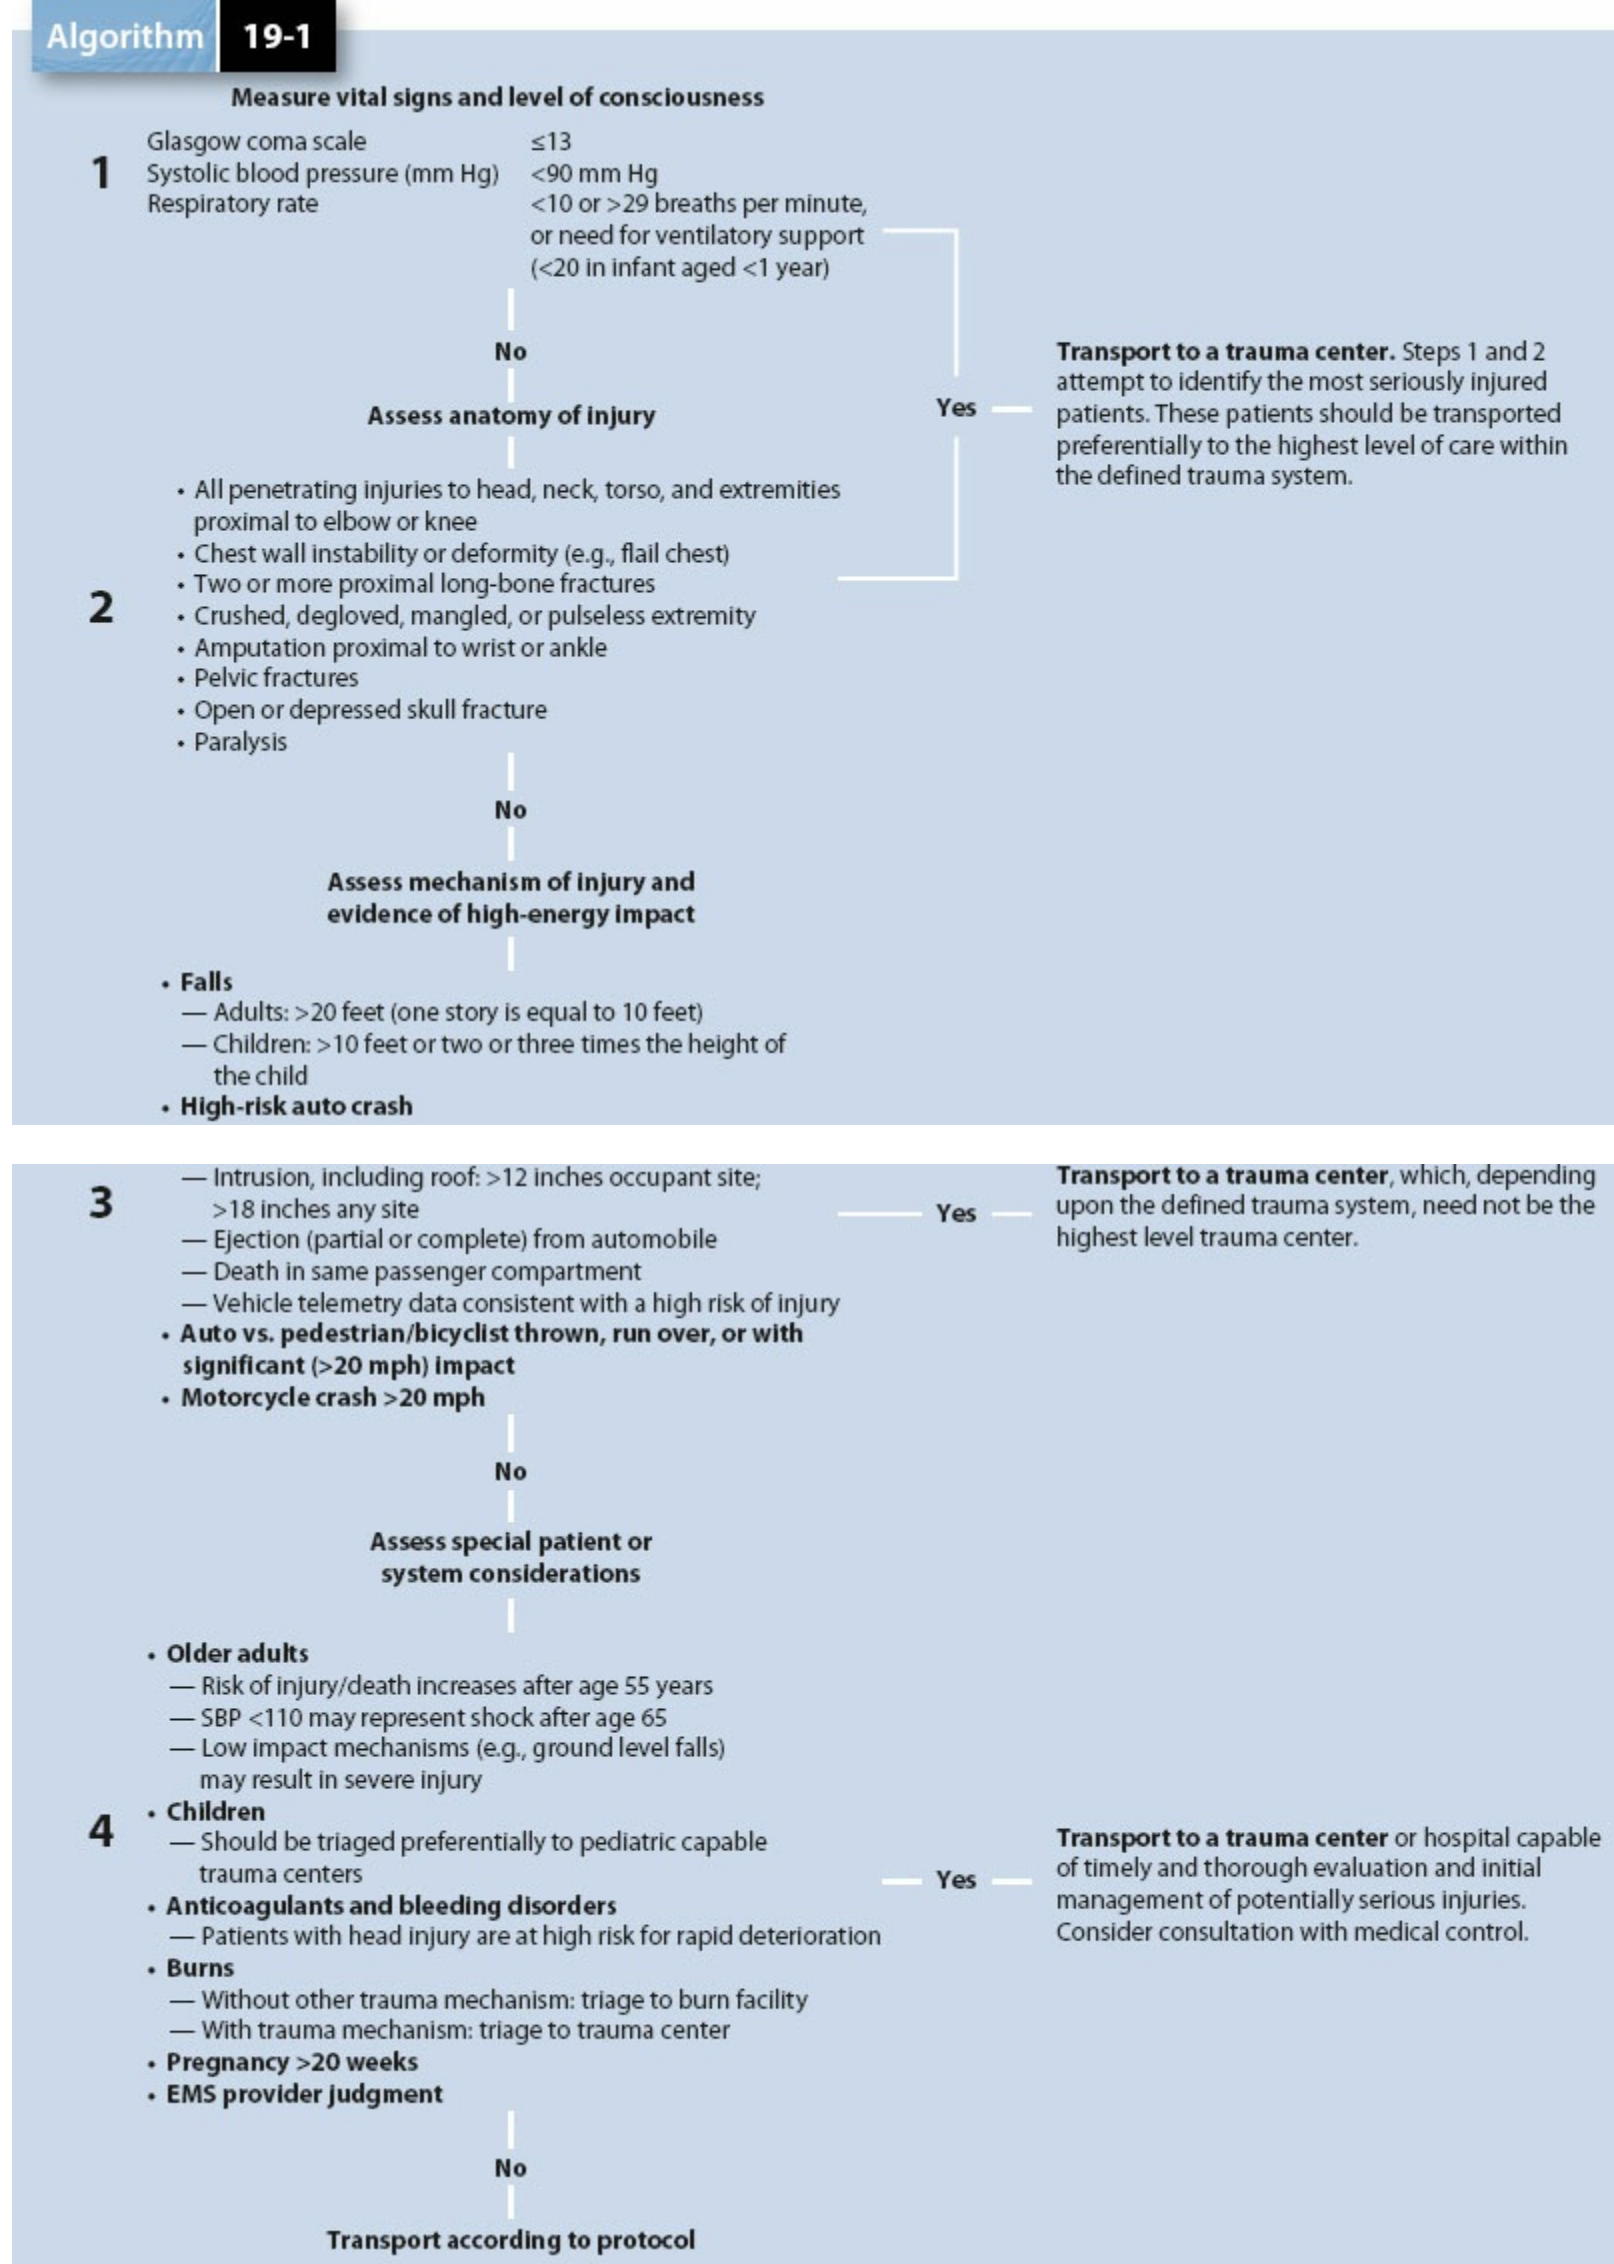

the sources of bleeding can be multiple and not always surgically fixable in the blunt trauma victims. Because of all these reasons, limited volume (“controlled”) resuscitation rather than no resuscitation is logical in this population. This is also supported by an early pilot prospective randomized trial where 192 patients with an out-of-hospital systolic blood pressure (SBP) of 90 mm Hg or lower were randomized to receive controlled resuscitation (CR) or standard resuscitation (SR).⁴⁷ CR patients received 250 mL of fluid if they had no radial pulse or an SBP of lower than 70 mm Hg, and additional 250-mL boluses were given only to maintain a radial pulse or an SBP of 70 mm Hg or greater. The SR group patients received 2 L initially and additional fluid as needed to maintain an SBP of 110 mm Hg or greater. This protocol was maintained until hemorrhage control or 2 hours after arrival in the hospital. The results showed that among the cohort of patients with blunt trauma, 24-hour mortality was 3% and 18% in CR and SR groups, respectively, with an adjusted odds ratio of 0.17(0.03 to 0.92).⁴⁷ At present, published data only support careful small volume crystalloid resuscitation to keep the injured alive during transport, and aggressive crystalloid resuscitation should be avoided. In the future, preserved blood products or specialized life-saving drugs may become available, but for now rapid transport to a specialized trauma center (“scoop and run”) is the most reasonable strategy in urban environments where the transport times are relatively short. In fact, a prospective comparison between Advanced Life Support (ALS) and Basic Life Support (BLS) transport⁴⁸ showed that patients transported by ALS units more often underwent prehospital interventions (97% vs. 17%; $p < 0.01$), including endotracheal intubation, needle thoracostomy, cervical collar, IV placement, and crystalloid resuscitation. While ALS ambulance on-scene time was significantly longer than that of BLS ($p < 0.01$), and had more prehospital interventions (1.8 ± 1.0 per ALS patient vs. 0.2 ± 0.5 per BLS patient; $p < 0.01$), 69.5% ALS patients and 88.4% of BLS patients ($p < 0.01$) survived to hospital discharge. The message is clear – less is more in the prehospital arena, and time to definitive care is the most critical variable. Others studies also support the argument that rapid transport to the trauma center is more important than prehospital interventions in urban victims of penetrating trauma.⁴⁹

Table 19-5 Criteria for Consideration of Transfer from Level III Centers to Level I or II Centers

1. Carotid or vertebral arterial injury.
2. Torn thoracic aorta or great vessel.
3. Cardiac rupture.
4. Bilateral pulmonary contusion with $\text{PaO}_2\text{:FiO}_2$ ratio less than 200.
5. Major abdominal vascular injury.
6. Grade IV or V liver injuries requiring transfusion of more than 6 U of red blood cells in 6 hours.
7. Unstable pelvic fracture requiring transfusion of more than 6 U of red blood cells in 6 hours.
8. Fracture or dislocation with loss of distal pulses.
9. Penetrating injuries or open fracture of the skull.
10. Glasgow Coma Scale score of less than 14 or lateralizing.
11. Spinal fracture or spinal cord deficit.
12. Complex pelvis/acetabulum fractures.
13. More than two unilateral rib fractures or bilateral rib fractures with pulmonary contusion (if no critical care consultation is available).
14. Significant torso injury with advanced comorbid disease (such as coronary artery disease, chronic obstructive pulmonary).

EARLY HOSPITAL CARE AND PRIORITIES

The Advanced Trauma Life Support (ATLS) program has put together a systematic, concise approach to the care of a trauma patient. ATLS was developed by the American College of Surgeons, Committee on Trauma (COT) and was first introduced in 1980, and is now taught in 60 countries across the world. The

ATLS program provides participants with a safe, reliable method for immediate management of the injured patient and the basic knowledge necessary to:

1. Assess the patient's condition rapidly and accurately
2. Resuscitate and stabilize the patient according to priority
3. Determine if the patient's needs exceed a facility's capacity
4. Arrange appropriately for the patient's interhospital transfer (who, what, when, and how)
5. Assure that optimum care is provided and that the level of care does not deteriorate at any point during the evaluation, resuscitation, or transfer process.

The basic concepts of ATLS include a primary survey focusing on the ABCDE (airway, breathing, circulation, disability, and exposure) to identify and address the life-threatening issues, followed by a secondary survey to identify all the injuries. The specific treatments of various injuries have been addressed in the different chapters that follow. However, the key points to emphasize are that the two main killers during the early hospital period ("golden hour") are the same as the prehospital setting – *bleeding and TBI*. As treatments for TBI remain mostly supportive, bleeding remains the number 1 cause of *preventable* deaths during the first 6 hours following trauma. In a bleeding patient, the priorities are to identify and control the source of bleeding in the shortest possible period of time. Sometimes the bleeding source is obvious and can be controlled by direct compression (e.g., stab wound to the femoral artery in the groin), tourniquets (e.g., mangled extremity), or sutures (e.g., scalp laceration), but often it is inside a body cavity. Localization of the hemorrhage source is relatively easy for penetrating trauma that is limited to a specific body region, but is notoriously difficult in the blunt polytrauma patients. In these patients, it helps to remember that a person can only lose significant volumes of blood in five locations: (1) pleural space, (2) intra-abdominal, (3) pelvis/retroperitoneal space, (4) soft tissues at the site of long bone fractures/sheer injuries, and (5) externally. With a quick examination and a chest x-ray, three of these possibilities can be easily ruled out, and the choice typically comes down to deciding between the abdomen and the pelvis. If the pelvic x-ray shows a significant pelvic fracture then the possibility of pelvic bleeding source is significant, and a pelvic binder should be applied promptly (or pelvis wrapped tightly with a sheet) for appropriate fracture patterns (e.g., suitable for open book fracture but potentially harmful for severe lateral compression). Focused assessment with sonography for trauma (FAST) can also be helpful in determining the source of hemorrhage. If it shows free fluid in the abdomen in a hypotensive patient then emergent laparotomy for hemorrhage control is justified. However, FAST has been reported to have a significant false negative rate even in experienced hands.⁵⁰ Although diagnostic peritoneal lavage has largely been abandoned, a bedside diagnostic peritoneal aspiration (DPA) can be very helpful in these patients. Percutaneous DPA can be performed in 1 minute, and it has been shown to be accurate, safe, and superior to FAST for the diagnosis of abdominal blood as the source of hemodynamic instability in multitrauma patients.⁵¹ In addition to hemorrhage control, massive transfusion protocol (MTP) should be activated in patients that are actively bleeding to avoid development of trauma associated coagulopathy (TAC). Normal coagulation homeostasis depends on a delicate balance between clot formation and breakdown. Normally, trauma tilts the balance in favor of clot formation at the site of injuries to stop the bleeding. However, major injuries, excessive blood loss, prolonged tissue hypoperfusion, and TBI with disruption of the blood–brain barrier have all been shown to upset the normal coagulation homeostasis, resulting in TAC.^{52,53} This can manifest as abnormal clot formation and/or excessive or rapid clot breakdown (fibrinolysis). Unless treated promptly, this coagulopathy leads to further bleeding, which sets up a vicious cycle resulting in the "lethal triad" of coagulopathy, acidosis, and hypothermia that is associated with an extremely high mortality.⁵⁴ An analysis of trauma-associated coagulopathy suggests that depletion coagulopathy results in abnormalities of traditional coagulation parameters (international normalized ratio, partial thromboplastin time) and predicts mortality, whereas fibrinolytic coagulopathy predicts infection, end-organ failure, and mortality, without a detectable difference in international normalized ratio or partial thromboplastin time.⁵⁵

Damage Control Resuscitation (DCR) or Hemostatic Resuscitation has recently emerged as a potential solution for the prevention and reversal of trauma-associated coagulopathy.^{30,56,57} This approach advocates early hemorrhage control, permissive hypotension (until control of hemorrhage), avoidance of crystalloids, and early use of blood components such as fresh frozen plasma (FFP) and platelets (in 1:1 or 1:2 ratios). A recent prospective randomized multi-institutional trial enrolled 680 patients with severe trauma and major bleeding to test two different blood component ratios.²² In this study, early administration of plasma, platelets, and red blood cells in a 1:1:1 ratio compared with a 1:1:2 ratio did

not result in significant differences in mortality at 24 hours or at 30 days. However, more patients in the 1:1:1 group achieved hemostasis and fewer experienced death due to exsanguination by 24 hours.²² It must be emphasized, however, that high-ratio protocols do not improve survival in patients who do not require massive transfusion (10 U of packed red blood cells [PRBCs] in 24 hours).⁵⁸ In fact, inappropriate infusion of plasma in patients who are not massively bleeding can worsen their outcomes.⁵⁹ So, while the exact ratio of PRBCs to FFP and platelets may be debatable, contemporary resuscitation practices have moved to early delivery of component therapy in the setting of massive bleeding, using standardized protocols (see below). Also, it should be emphasized that resuscitation is an adjunct to early hemorrhage control and not a substitute. In a bleeding patient, initiating DCR is a great idea, but the patient's eventual survival depends on the ability (or inability) to obtain rapid and reliable hemorrhage control. In addition, prevention and active reversal of hypothermia (e.g., use of fluid warmers, body warming devices) and correction of acidosis and hypocalcemia are critically important while resuscitation protocols are carried out.

We also know that development of a clot is just the initial part of the process, and rapid breakdown of the clot may be equally detrimental. It has been shown that development of fibrinolysis is a highly lethal event in severely injured patients,^{60,61} and treatment with blood products alone is incapable of reversing this process. Despite ongoing debate about precise ratios of blood products,⁶² there is general agreement that blood products should be administered in the form of a MTP to optimize the processes of care and to improve outcomes. Cotton et al.⁶³ tested the effectiveness of a trauma exsanguination protocol by comparing patients treated with the protocol ($n = 94$ over 18 months) to a cohort of similar patients admitted during the prior 18 months ($n = 117$). The study found that implementation of the protocol reduced 30-day mortality (51% vs. 66%, $P < 0.03$), decreased intraoperative crystalloid administration (4.9 L vs. 6.7 L, $P = 0.002$), and reduced postoperative blood product use (2.8 U of PRBCs vs. 8.7 U, $P < 0.001$; 1.7 U of FFP vs. 7.9 U, $P < 0.001$; 0.9 U of platelets vs. 5.7 U, $P < 0.001$). Dente et al.⁶⁴ conducted a similar study of an MTP (1:1:1 ratio of platelets, FFP, and PRBCs) by comparing matched patients during a 1-year period before and after implementation of protocol (73 patients in the protocol group and 84 matched controls). Implementation of the protocol was found to reduce mortality in the first 24 hours (17% with MTP vs. 36% pre-MTP, $P = 0.008$) and at 30 days (34% vs. 55%, $P = 0.04$), with a more pronounced impact in the patients with blunt trauma.⁶⁴ This study also showed that MTP patients required fewer overall transfusions of PRBCs and FFP after the first 24 hours (2.7 vs. 9.3 U of PRBCs, $P < 0.0001$; 3 vs. 7.5 U of FFP, $P < 0.05$). The University of Michigan MTP is provided for reference (Fig. 19-8).⁶⁵ It should be emphasized that to be effective these protocols should not only incorporate the best available evidence, which is constantly changing, but also reflect the resources and realities of the individual institutions.

LESSONS LEARNED FROM THE BATTLEFIELD

7 Every major war has catalyzed rapid advances in trauma care. As the medical systems grapple with the challenges of taking care of massive numbers of injured people (military and civilian), often in very austere settings, they quickly evolve, adapt, and improvise. Wars also prompt significant financial investment by the governments in research and development, and attract some of the best minds to the field. Many of the things (various operative interventions, drugs, fluids, dressings, rapid transport systems, trauma teams, in-field care, and many more) that are taken for granted today in the civilian trauma centers can be traced back to the wars of the past. Interestingly, as the war medicine improves and evolves to take care of worse injuries, the war industry responds by developing more lethal weaponry. Thus, the percentage of injured that die in the battlefield (Killed in action or KIA rate) has remained relatively static during the 20th century, hovering around 25% (Table 19-6). The current conflict is the first time in modern warfare that the KIA rate has dropped down to 10%.^{66,67} This dramatic drop is clearly multifactorial in etiology, and reflects the focus on prevention strategies with widespread use of superior protective body armor, and deployment of better-designed military vehicles. In addition, the current ongoing conflicts have fundamentally altered how we take care of the injured, which has resulted not only in improved survival rates but also markedly superior functional outcomes. A brief list of the key advancements would include the following:

- Prevention:** Explosions (many due to improvised explosive devices or IEDs) have caused a greater percentage of injuries in Iraq and Afghanistan than in any other large-scale conflict. Compared to historical data, improvements in body armor have clearly changed the injury profile of the service personnel.⁶⁸ Kevlar helmets, protective eyewear, and body armor is now routinely used. Many direct hits to the to the head and torso that used to be lethal in the previous wars are now potentially survivable. TBI has become the “signature injury” of the current conflict, but increasingly large numbers of individuals survive these injuries. An analysis of 4,623 combat explosion episodes in Iraq

between March 2004 and December 2007 showed that the most frequent single injury type was a mild TBI (10.8%).⁶⁹ Other frequent injuries were open wounds in the lower extremity (8.8%) and open wounds of the face (8.2%), which includes tympanic membrane rupture. The extremities were the body regions most often injured (41.3%), followed by head and neck (37.4%) and torso (8.8%). Majority of the explosions resulted in more than one injury, and the variety of injuries across nearly every body region and injury type reflects the complex nature of explosion injuries. The fact that large number of US military personnel involved in these explosions survive is a testament to the sophisticated vehicle and personal body armor that is being used by the US and NATO forces, and to superb medical care. For example, mortality from direct chest trauma has dropped down to 10% with the most common injury pattern being pulmonary contusion rather than lethal injury to the critical organs.⁷⁰

- b. *Early hemorrhage control:* This is another area where we have seen major improvements. At the start of the conflict the battlefield dressings that were in the individual first aid kits were not a whole lot different from the ones used by the Roman Legions centuries ago. Cotton-based compression dressings and tourniquets had not changed much until the start of the conflict but then underwent a very rapid evolution. A number of advanced hemostatic bandages were quickly developed, rigorously tested, and expeditiously deployed by the military.⁷¹ These advanced hemostatic dressings were widely used during the early years of the Iraq and Afghanistan wars and saved many lives. Since then, second generation dressings have been developed and tested,⁷² and incorporated into the Tactical Combat Casualty Care (TCCC) guidelines.^{73,74} Many of these dressings that were developed for military use are now widely available, and are commonly used by the civilian emergency medical response providers. When anatomically possible, even more secure hemorrhage control can be obtained by placing a tourniquet. A review of 10 years of data from a military registry showed that of 4,297 casualties with extremity trauma, 30% underwent application of tourniquets.⁷⁵ Over this period, tourniquet use increased by 10-fold, and survival rates improved markedly for casualties that had injuries suitable for tourniquets. Typical tourniquets are not effective for really proximal injuries,⁷⁶ but in recent years, a number of junctional tourniquets have been developed, and two of these [Combat Ready Clamp (CRoC; <http://www.combatmedicalsyste.ms.com>) and SAM Junctional Tourniquet (SJT; <http://www.sammedical.com/products>)] performed well when tested by military medics.⁷⁷ Development of advanced dressings and new military tourniquet (windlass devices that can be self-applied and tightened using a single hand) has changed early battlefield care.⁷⁸ However, civilian trauma systems have been alarmingly slow in adopting these lessons and developing uniform guidelines.⁷⁹ This was at full display after the Boston Marathon bombing when most of the tourniquets used were improvised (and inefficient) devices rather than the military versions.⁸⁰ Our experiences with mass casualties underline how important it is for all the emergency medical personnel and physicians to learn the proper use of tourniquets and advanced hemostatic dressings. Austere military settings with focus on damage control procedures have also generated interest in the use of intraluminal occlusive balloons.⁸¹ A variety of balloons and catheters have historically been used by trauma and vascular surgeons for the temporary control of bleeding. Recently, this concept has been taken to the next level as a result of collaborative efforts between the civilian and military surgeons, where the aorta (thoracic or abdominal) is controlled with the bedside application of a resuscitative endovascular balloon occlusion of the aorta (REBOA) device.⁸² The balloon-carrying catheter can be inserted using percutaneous techniques, typically via the femoral artery, advanced (without need for fluoroscopy) into the aorta, and inflated to interrupt the aortic flow below the balloon. In this way, REBOA functions essentially similar to an aortic cross-clamp that is applied during resuscitative thoracotomy. Although these tools are not yet widely used, courses have been developed to teach these new life-saving skills to the surgical community.⁸³ While the strategy is promising,⁸⁴ and good results have been reported by the US trauma centers,⁸⁵ data from Japan where emergency medicine physicians typically use the REBOA technology have shown some concerning outcomes.⁸⁶ Wider use would require additional work to identify the best target population, the most effective method for deployment, and optimal training requirement for the users.

Table 19-6 Lethality of War Wounds among US Soldiers

	No. Wounded or Killed in Action	No. Killed in Action	Lethality of War Wounds (%)
Revolutionary War, 1775–1783	10,623	4,435	42
War of 1812, 1812–1815	6,765	2,260	33
Mexican War, 1846–1848	5,885	1,733	29
Civil War (Union Force), 1861–1865	422,295	140,414	33
Spanish–American War, 1898	2,047	385	19
World War I, 1917–1918	257,404	53,402	21
World War II, 1941–1945	963,403	291,557	30
Korean War, 1950–1953	137,025	33,741	25
Vietnam War, 1961–1973	200,727	47,424	24
Persian Gulf War, 1990–1991	614	147	24
Current conflicts*, 2001–April 29, 2016	52,432	5,387	10

*Includes data reported publicly by the Department of Defense that are available at <http://www.defense.gov/casualty.pdf>. Last accessed on April 29, 2016. These data include the following military operations: OPERATION IRAQI FREEDOM, OPERATION NEW DAWN, OPERATION ENDURING FREEDOM, OPERATION ENDURING FREEDOM, OPERATION INHERENT RESOLVE, OPERATION FREEDOM'S SENTINEL.

c. *DCR/Prevention and treatment of coagulopathy*: Just like massive crystalloid resuscitation has been associated with the Vietnam war, where “shock lung/Da Nang lung” (later termed acute respiratory distress syndrome or ARDS) was first described in soldiers that received massive crystalloid resuscitation, the current conflict would be remembered for advancing the concept of DCR. The pendulum has clearly swung toward balanced resuscitation, in large parts based upon the battlefield resuscitation practices. It is informative to briefly review how our clinical practices changed during the war even in the absence of good class I/II clinical evidence. It should also be pointed out that logistical issues (weight, volume, storage requirements etc.) are often a major driver of change in the military. Historically, many DoD agencies, such as the Office of Naval Research (ONR), the US Army Medical Research and Material Command (MRMC), and Defense Advanced Research Projects Agency (DARPA) just to name a few, have been long-standing sponsors of resuscitation research. Primarily as a result of leadership and funding by the ONR, three significant consensus conferences were held where experts analyzed the available data on fluid resuscitation, and recommendations were made to improve clinical practice and to guide future research. The first meeting was held under the supervision of the Institute of Medicine (IOM) in 1998. The IOM report concluded that the current resuscitation strategies were inadequate, potentially harmful, and needed radical changes. It identified numerous areas of future research, and recommended that combat casualties should be resuscitated with 250 mL bolus of 7.5% saline.⁸⁷ Unfortunately, the US Food and Drug Administration (FDA) had not approved this fluid for clinical use. In the follow-up meeting (June 2001, Uniformed Services University, Bethesda, MD) a number of clinical recommendations were made including who should (and should not) be resuscitated, appropriate end points of resuscitation, as well as the optimal fluid for resuscitation.⁸⁸ As the choice was deliberately limited to FDA-approved agents (available in the United States), Hetastarch (hydroxyethyl starch) was narrowly recommended as the fluid of choice for use in the battlefield. In the third meeting (October 2001, Toronto, Canada), the scope was widened to include fluids that were available in the NATO countries (even if not available in the United States).⁸⁹ At that meeting a combination fluid (7.5% saline and 6% dextran-hypertonic saline dextran) was recommended as the initial fluid of choice.⁹⁰ At all of these meetings experts agreed that aggressive resuscitation is deleterious, an “ideal” fluid is yet not available, and that low-volume resuscitation (hypertonic, colloid, or combination) is the most logical choice for the military needs. Proceedings of the last two meetings were published as a special supplement of the *Journal of Trauma* (May 2003), including the recommendations for the initial fluid resuscitation of combat casualties.⁹¹ Over the next decade, the concepts of DCR became more well established, and this change is clearly reflected in the latest recommendations by the Tactical Combat Casualty Care guidelines for Fluid Resuscitation for Hemorrhagic Shock⁹²: “(1) dried plasma (DP) is added as an option when other blood components or whole blood are not available; (2) the wording is clarified to emphasize that Hextend is a less desirable option than whole blood, blood components, or DP and should be used only when these preferred options are not available; (3) the use of blood products in certain Tactical Field Care (TFC) settings where this option might be feasible (ships, mounted patrols) is discussed; (4) 1:1:1 DCR is preferred to 1:1 DCR when platelets are available as well as plasma and red cells; and (5) the 30-minute wait between increments of resuscitation fluid administered to achieve clinical improvement or target blood pressure (BP) has been eliminated. Also

included is an order of precedence for resuscitation fluid options. Maintained as recommendations are an emphasis on hypotensive resuscitation in order to minimize (1) interference with the body's hemostatic response and (2) the risk of complications of over resuscitation. Hextend is retained as the preferred option over crystalloids when blood products are not available because of its smaller volume and the potential for long evacuations in the military setting." It should be pointed out that although these guidelines have been designed specifically for the battlefield environment, many of these recommendations are now becoming an integral part of the civilian trauma care (e.g., avoidance of crystalloids, early blood product use, high ratios of plasma and platelets to red cells). Many of the landmark studies such as PROMMTT⁵⁷ and PROPPR,²² were also supported by the DoD funds, and their findings have significantly changed our practices. Another area where military data have advanced the field is in defining the appropriate use of antifibrinolytic agents. An organized clot, histologically, is a clump of blood cells in a mesh of fibrin strands, which is the final product of the coagulation cascades. Plasmin breaks down the fibrin strands to initiate clot resolution. Normally, clot formation and breakdown are precisely balanced to prevent excessive thrombosis or coagulopathy. Trauma-associated coagulopathy disrupts this balance and leads to poor clot formation and rapid breakdown. Antifibrinolytic drugs such as aprotinin, tranexamic acid (TXA), and ϵ -aminocaproic acid stabilize the blood clot, which can slow down the bleeding. Due to safety concerns, aprotinin was withdrawn from world markets in May 2008, but TXA and ϵ -aminocaproic acid are in fairly wide clinical use and appear to be free of serious adverse effects.⁹³ TXA is a lysine analog that binds with plasminogen to prevent its activation,⁹⁴ and in higher concentrations is a noncompetitive inhibitor of plasmin (actions similar to those of ϵ -aminocaproic acid but about 10 times more potent in vitro). In the recent Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH-2) trial,²⁷ which is one of the largest prospective randomized trials in trauma patients, 20,211 patients at 274 hospitals in 40 countries (mostly underdeveloped) were randomized to receive either TXA or placebo within 8 hours of injury. All-cause mortality in TXA-treated patients was significantly lower compared with placebo (14.5% and 16% in TXA and control groups, respectively; $P = 0.0035$), as was the risk due to bleeding (4.9% and 5.7% in TXA and control groups, respectively; $P = 0.0077$). Subgroup analysis showed that the benefit was found only in patients who were given the drug early (within 3 hours of injury) and were severely hypotensive ($SBP \leq 75$ mm Hg). Skeptics point out that the overall survival improvement, although statistically significant, was rather modest (1.5%). There were some other concerns, including the fact that only half the patients in this study required any blood transfusion, suggesting that most were not severely injured. As this study was conducted in developing countries where DCR is not in common use, it is unclear how the results would be influenced by early use of blood component therapy. Critical data about the physiological status of the patients, monitoring methods, blood loss, imaging studies, operative interventions, and complications were not gathered. Also, the role of TXA in the setting of TBI was not determined as only one-third of the patients had a Glasgow Coma Scale score of 12 or lower on admission. Finally, this study was not designed to identify underlying protective mechanisms. These limitations led some experts (military and civilian) to question the robustness and generalizability of the findings, especially in the setting of massive bleeding.⁹⁵ In this area of uncertainty, new data from the battlefield have helped clarify the way forward. One important study was a retrospective observational analysis of prospectively collected data in 896 battlefield casualties (377 civilian and 519 military patients) who received at least 1 U of PRBCs (within 24 hours of admission) at a military hospital in Afghanistan.⁹ A third of the patients received massive transfusion (≥ 10 units of PRBC). Unadjusted mortality rates were lower in TXA-treated patients (17.4% and 23.9% in TXA and no-TXA groups, respectively; $P = 0.03$). The benefit was most pronounced in patients who received massive transfusion (14.4% and 28.1% in TXA and no-TXA groups, respectively; $P = 0.004$). TXA was also independently associated with higher odds of survival (odds ratio = 7.2) and less coagulopathy ($P = 0.003$). A follow-up study (Military Application of Tranexamic Acid in Trauma Emergency Resuscitation [MATTERS II]) showed that the addition of cryoprecipitate independently added to the benefits of TXA in the seriously injured in the battlefield.⁹⁷ A closer look at the data from these studies raises some potential safety concerns. In CRASH-2, mortality due to bleeding increased if TXA treatment was given after 3 hours (3.1% and 4.4%, in < 3 hours and > 3 hours, respectively; $P = 0.0049$). In the MATTERS trial, a statistically significant increase was noted in pulmonary embolism (TXA 2.7% vs. no TXA 0.3%, $P = 0.001$) and deep venous thrombosis (TXA 2.4% vs. no TXA 0.2%, $P = 0.001$). It is unclear whether this simply reflects sicker patients in the TXA group or a real increase in the incidence of adverse events. Experts in the field have therefore

developed evidence-based guidelines for the use of TXA⁹⁸ that recommend the use of TXA in adult trauma patients with severe hemorrhagic shock (SBP <75 mm Hg), with known predictors of fibrinolysis, or with documented fibrinolysis on thromboelastography. In these patients, TXA should be administered only if the time from injury is less than 3 hours, and the dose of TXA should be 1 g over 10 minutes followed by another 1-g IV infusion over 8 hours. Although we are likely to see ongoing debates about the concepts of DCR and whether and when to use adjunctive agents such as TXA, cryoprecipitate, desmopressin, and prothrombin complex concentrates, the research supported either directly or indirectly by the military over the last 10 to 15 years has clearly changed how we treat the massively bleeding patients today (Fig. 19-8).

- d. *Rapid Evacuation and Long-distance Transport:* Rapid air evacuation by specially trained teams was popularized by the US military in the Korean War with great results. Although the war patterns have changed to be more urban, nonlinear, and with a smaller foot-print, rapid evacuation is no less important in the current era. In fact, after the US Secretary of Defense Robert M. Gates mandated in 2009 that the prehospital helicopter transport of critically injured combat casualties should be 60 minutes or less, the evacuation systems became even more efficient. An analysis of battlefield data (21,089 US military casualties) before and after the mandate showed that for the total casualty population, the percentage killed in action (16.0% [386 of 2411] vs. 9.9% [964 of 9755]; $P < 0.001$) and the case fatality rate ([CFR] 13.7 [469 of 3429] vs. 7.6 [1344 of 17660]; $P < 0.001$) were higher before versus after the mandate, while the percentage died of wounds (4.1% [83 of 2025] vs. 4.3% [380 of 8791]; $P = 0.71$) remained unchanged.⁹⁹ Decline in CFR after the mandate was associated with an increasing percentage of casualties transported in 60 minutes or less (regression coefficient, -0.141 ; $P < 0.001$), with projected versus actual CFR equating to 359 lives saved. Among 4,542 casualties (mean injury severity score, 17.3; mortality, 10.1% [457 of 4542]) with detailed data, there was a decrease in median transport time after the mandate (90 min vs. 43 min; $P < 0.001$) and an increase in missions achieving prehospital helicopter transport in 60 minutes or less (24.8% [181 of 731] vs. 75.2% [2867 of 3811]; $P < 0.001$). Even more impressive are the results of long-distance transport. One of the unique aspects of the military medical care system that emerged during Operation Iraqi Freedom and Operation Enduring Freedom has been the opportunity to apply existing civilian trauma system standards to the provision of combat casualty care across an evolving theater of operations. Review of the Critical Care Air Transport Team (CCATT) and Joint Theater Trauma Registry databases shows that for severely injured (mean ISS 23.7) that were evacuated to Landstuhl Regional Medical Center in Germany, the en route mortality rate was less than 0.02%.¹⁰⁰ This is a huge testament to the superb skills, tools, training, and resources that the military has provided for the care of the injured. It also proves that rapid movement of critically injured casualties within hours of wounding appears to be effective, with a minimal mortality incurred during transport and overall 30-day mortality of 2%.¹⁰⁰ Many of these lessons will be translated into the general trauma practice as these medics and physicians transition to civilian work.
- e. *Rehabilitation:* Lower-extremity injuries continue to be the most common injuries in the current conflict. In fact, they account for 60% of all injuries to the US troops in Iraq and Afghanistan, which are to the lower extremities, mostly due to explosive devices.¹⁰¹ But unlike previous wars, the tools and technologies available today are markedly different. Not only are temporary vascular shunts being used widely,^{102,103} but also early vascular reconstruction is being performed more frequently with excellent outcomes.^{104,105} Liberal use of temporary vascular shunts to control bleeding and restore distal flow during transport to higher echelons of care is clearly a logical approach. It is also a practical solution when dealing with combined vascular and orthopedic injuries, and when the surgeon providing the initial care lacks the skills to perform the definitive vascular repairs.¹⁰⁶ Development and implementation of comprehensive rehabilitation strategies,¹⁰⁷ and cutting edge technology in prosthetic limbs¹⁰⁸ to treat the injured service members with complex lower-extremity trauma from combat has resulted in some of the best functional outcomes in the history of warfare. The civilian trauma system would clearly be the beneficiary of these developments in the future.

NEW DEVELOPMENTS IN INTRACAVITY HEMORRHAGE CONTROL

Current trauma training and equipment is sufficient to care for 53% of the potentially survivable deaths, but novel methods of intravenous or intracavitary noncompressible hemostasis (combined with rapid surgery) are required for the remaining 47% of the decedents.¹⁰⁹ This is the next frontier in hemorrhage

control, and many researchers are addressing the challenge of controlling intracavity bleeding especially in the prehospital setting. There was some initial enthusiasm for using systemic therapies such as recombinant clotting factors (factor VIIa), but randomized clinical trials have failed to show a benefit in trauma patients.¹¹⁰ Recently, the focus has shifted to local/mechanical methods. In addition to devices such as REBOA,⁸⁶ approaches such as expanding foams,^{111,112} insufflation,¹¹³ and compression devices¹¹⁴ are being tested. If successful, these could be the game changers that we have been looking for decades.

FUTURE DIRECTIONS

Despite numerous advances, we have failed to make a significant impact on the early trauma deaths. Many of these individuals have underlying injuries that are potentially survivable, but they die before getting definitive care. While resuscitation restores tissue perfusion, it does not have any specific pro-survival properties. By the time the injured gets to the hospital nothing can be done to reverse the “irreversible shock.” A much more exciting approach would be to improve the survival by administering specific pharmacological agents in the field that could immediately upregulate pro-survival genes and proteins to create a *pro-survival phenotype*,¹¹⁵ or use strategies to induce a state of “suspended animation” to keep the organs preserved until the source of hemorrhage can be controlled.^{116,117}

In the not too distant future, early trauma resuscitation may be very different from what we currently practice. In addition to early hemorrhage control and DCR, we are also likely to see:

- a. Use of specific pro-survival drugs that can be given in the prehospital setting to keep the injured alive long enough to get evacuated to higher levels of care (effective “bridge to definitive care”).
- b. Early use of preserved plasma products, platelets, and red blood cells.
- c. Availability of blood “farming” to eliminate the logistical barriers to supply.
- d. Development of safe and effective nonblood oxygen carrying fluids that can be easily administered.
- e. Ability to temporarily “suspend” life using hypothermia or hibernation strategies for patients that have potentially survivable injuries, but need more time for surgery or transfer.
- f. Individualized therapy with administration of specific pharmacological agents based upon the individual’s cellular disturbances.
- g. Monitoring of response to therapy that goes beyond measurement of physiology, and looks at the reversal of cellular disturbances.

Chapter 20

Prehospital and New Advances in Resuscitation

John R. Taylor III, John B. Holcomb, and Bryan A. Cotton

Key Points

- 1 Prehospital care is an evolving field with more options to get early treatment to acutely injured patients.
 - 2 Prehospital care does not have to be done by EMS personnel only; the emphasis is now on care given by other citizens on site.
 - 3 Early and aggressive blood product resuscitation has transformed how we care for critically injured patients.
 - 4 Technologic advances to include end-tidal CO₂ monitoring, ultrasound, tourniquets, and REBOA will continue to advance the field.
 - 5 Further research into optimal type, timing, and amount of resuscitative fluid will change how we treat our patients in the field.
-

INTRODUCTION

Trauma continues to be the leading cause of death for 1 to 44 year olds and is the overall fifth leading cause of death for all age groups.¹ The care of the injured patient is a tightly integrated exercise combining the expertise of the prehospital care team and the trauma team once they arrive at the hospital. The likelihood of patient survival is vastly increased by timely transport and proper intervention in the acutely injured patient. The care of the injured patient begins immediately following injury. This may be rendered initially by nearby civilian bystanders or a variety of trained first responders. The recently published Hartford Consensus III outlines that it is the shared responsibility of the medical professionals as well as the noninjured, or minimally injured, patients at the scene to provide care to those injured, specifically addressing cessation of ongoing hemorrhage.² The main goal of a prehospital system is to provide timely appropriate care for the sick or injured patient and get them to the most appropriate hospital for definitive care as quickly and safely as possible. At times the most appropriate hospital may be the closest and at others it may be more distant, but with the capabilities more suitable to a particular patient. Most commonly, a phone call placed to a 9-1-1 dispatcher activates the emergency medical system (EMS) and quickly allocates resources to the location where help is needed.

PREHOSPITAL CARE

Personnel

Prehospital personnel are comprised of emergency medical technicians (EMTs), paramedics, firefighters, police, nurses, and less commonly physicians. The recently released Hartford Consensus III places nonmedical civilians on the forefront of hemorrhage control as a ready force of immediate responders. There are multiple levels of EMTs. The EMT-B or basic level has training capable of providing basic life support (BLS). BLS maneuvers include external hemorrhage control, spine immobilization, noninvasive cardiopulmonary resuscitation, and administration of supplementary oxygen, and application of an automated external defibrillator (AED). Paramedics require additional training, upward of 1200 hours, and may administer advanced life support (ALS) techniques. Prehospital ALS was first employed as a “mobile intensive care unit” in 1967.³ In addition to the maneuvers administered by BLS personnel an ALS unit can provide cardiac drugs, pain control, blood pressure management, glucose control, needle decompression of tension pneumothoraxes, and anticonvulsant medication. There is much debate as to

whether ALS is superior to BLS in the prehospital setting. Recent meta-analysis concluded that ALS provides a survival advantage only to nontrauma patients.⁴

In certain US cities a physician medical director of EMS is available at all times to respond to ground crews and dispatch centers for advice. The physician may also respond in person to certain calls as needed. Their role includes providing quality control, education, and approval of drug administration outside of set protocols. Outside of the United States some countries have full time physicians riding with ambulance crews at all time. While physician presence increases transport time there is evidence which indicates an increase in survival in patients with acute myocardial infarction and respiratory distress.⁵

Scoop and Run Versus Stay and Play

The two paradigms that dictate the amount and type of care that patients receive in the prehospital setting are the “Scoop and Run” and the “Stay and Play.” The overarching premise of the Scoop and Run technique is to get the injured patient to a facility that can provide definitive care in the shortest period of time. The proponents of this system cite the increasing amount of evidence that prehospital interventions are fraught with complications from both their intervention as well as the resultant delay in arriving at a trauma facility.⁶ Stay and Play advocates feel that the early control of life-threatening injuries is considered of critical importance in the management of the injured patient, and initiating therapy for such injuries in the prehospital environment may improve patient survival.⁷ The true answer to which paradigm is best for the patient most likely lies somewhere in the middle of the two. In an urban setting with readily accessible, and multiple, trauma facilities it makes sense to extract the patient and get them to the closest center, performing limited, but lifesaving interventions during transport. In a rural environment, where access to a hospital may be greatest distances by road or prolonged wait for rotary wing care, it may be best to provide care on site allowing for stabilization of the patient’s injuries. Further studies are necessary to decide which of these two paradigms provide the best care for the patient.

Table 20-1 Prehospital Assessments and Interventions

A	Chin-lift/jaw thrust, oropharyngeal airway, nasopharyngeal airway
B	LMA, king-tube, surgical airway, needle decompression, chest tube, capnography
C	Tourniquet, needle decompression, permissive hypotension, early blood products
D	C Spine immobilization, backboard placement, splinting of extremity fractures
E	Clothing removal, exposure of wounds, warming devices

SCENE ASSESSMENT AND MANAGEMENT PRIORITIES

Airway

1 It is paramount once on scene for the EMT to determine the status of the patient’s airway. Evaluating the patient’s Glasgow Coma Scale (GCS), chest rise, extent and nature of injuries provides vital insight into whether or not the patient is and will be able to maintain their airway (Tables 20-1 and 20-2). Supplemental maneuvers such as suctioning, chin lift/jaw thrust, placement of oropharyngeal airways, and use of bag-mask devices can temporarily restore oxygenation in the acutely injured patient. These maneuvers will usually maintain airway patency for the patient during their transport to definitive care; for those who are unable to do so, advanced airway maneuvers are key to securing a patent airway. Tracheal intubation provides a definitive airway with a cuffed endotracheal tube that will facilitate oxygenation, ventilation, and prevent aspiration. The skills required to successfully intubate are difficult to achieve and require remediation and oversight to maintain.⁸ There is conflicting literature to support field intubation. Winchell and Hoyt completed a retrospective review of blunt trauma patients with severe head injury in San Diego that found statistically significant decrease in mortality between patients intubated in the field and those who were not.⁶ The only randomized controlled trial of prehospital intubation versus bag-mask ventilation occurred in 2000 with pediatric patients, and it

showed that the addition of out-of-hospital intubation did not improve survival or neurologic outcomes.⁹ A retrospective review of prehospital intubation versus bag-mask ventilation by Stockinger and McSwain showed no survival advantage to intubation and an increased prehospital time.⁸ The majority of literature suggests that prehospital intubation does not improve survival and may prolong time to definitive care.¹⁰ One meta-analysis evaluating emergency intubation for the acutely ill showed no survival benefit in nontraumatic cardiac arrest prehospital intubation, as well as no evidence of prehospital intubation benefitting trauma patients in the urban environment.¹¹ While the majority of situations in the prehospital setting do not require intubation, there are some that make sense to secure an airway. Patients who have evidence of extensive facial trauma, patients who will require long transport times to reach definitive care, and those patients who are apneic due to suspected cervical injury are appropriate to intubate in the prehospital setting. The reflexive intubation to “protect” the airway should be avoided, and further randomized studies are required to truly answer the question of who and when to intubate in the prehospital setting.

Table 20-2 Listening to the Patient

Patient Complaint	Clinical Problem
“I can’t breathe!”	Ventilatory dysfunction
“I need to sit up!”	Hypoxia Ventilatory dysfunction Tamponade
“I can’t swallow!” “I’m choking!”	Airway dysfunction
“I’m gonna die!” “Please help me!”	Hypoxia Hemorrhage
“I’m thirsty!”	Hemorrhage

There are alternative measures that can be taken for those who need to establish an airway but do not have the skills for intubation. Laryngeal mask, Combitube, and King Airway all require less training and skill for insertion, however, they have never been shown to increase survival. While the invention of video-assisted airway insertion devices has taken hold in the hospital setting for “difficult” airways, its use in the prehospital setting has not been studied in depth. A retrospective review of patients in Europe showed the prehospital use of the Glidescope facilitated successful intubation when conventional direct laryngoscopy failed.¹² This study is limited by its small size and retrospective nature, however, as technology advances the use of video-assisted airway devices may allow for more successful prehospital intubation. Whether or not these devices will increase survival in patients is unknown at this time. A surgical cricothyroidotomy (CRIC) can provide an emergency airway in the hands of skilled practitioners. This maneuver requires much training and is usually utilized by military personnel in austere environments, or after failed orotracheal intubation efforts. A retrospective review by the Israeli Defense Force showed a 93% success rate with CRIC for patients requiring an emergency airway.¹³

Breathing

Assessment of patient’s breathing occurs simultaneously with airway assessment. Evaluation of symmetric chest rise, obvious signs of chest trauma, and presence of bilateral breath sounds give the first responder an idea of the patient’s status. The presence of a tension pneumothorax is a life-threatening event that may lead to obstructive shock, hemodynamic collapse, and potentially death. EMTs may also identify a patient with a tension pneumothorax with the presence of tracheal deviation, neck vein distention, and cyanosis. Prompt decompression of the thoracic cavity with a needle is necessary to reverse the tension effect. While the traditional landmark has been the midclavicular line, cadaver and computerized tomography evaluations had demonstrated more consistent evacuation of air using the anterior axillary, especially in females.¹⁴ Further management with tube thoracostomy will be evaluated once the patient arrives at their receiving facility. Large sucking chest wounds, that permit the rapid equilibration of pleural and atmospheric pressure, can be rapidly fatal. These wounds prevent the lung from expanding and preclude alveolar ventilation. These large wounds cause hemodynamic collapse rapidly unless an airway is obtained that allows for positive pressure ventilation. The very rare smaller open chest wounds are amenable to a three-sided dressing that allows for gas to exit from the chest wall defect but prevents gas from entering the chest wall. These can be fashioned in a field expedient manner and function as a temporizing action until definitive therapy with a chest tube, in a sterile environment, can be achieved.

In addition to gross disturbances and threats to oxygenation and ventilation, prehospital personnel should be aware of these specific interventions as occasionally they can lead to greater harm than the injury itself. Over the last decade, the trauma literature has shown that the manner in which we previously cared for the airway in traumatic brain injury (TBI) may have done more harm than good.^{15,16} Hyperventilation in the prehospital setting had been previously advocated, and is unfortunately still occasionally practiced, leading to acute vasospasm in the cerebral blood flow causing an overall decrease in the cerebral blood flow in patients with a severe TBI. This has since been abandoned in favor of normocapnea, decreasing the actual increase in overall cerebral blood flow (and worse outcomes) with hyperventilation.^{15,17} Warner et al. in the *Journal of Trauma* showed that end-tidal CO₂ monitoring in the prehospital setting poorly correlated with the actual arterial blood gas analysis pCO₂, and as such suggested that using it to guide prehospital ventilation status may lead to inadvertent hypercapnia.

Given that many prehospital personnel ventilate patients via bag-valve devices connected to either a facemask or directly to an endotracheal tube, experts in the field and numerous investigators have advocated for the use of end-tidal CO₂ monitoring in these settings.^{18,19} Silvestri et al. showed that there were no misplaced endotracheal tubes in patients who had continuous end-tidal CO₂ monitoring (0/93) whereas 23.5% of misplaced (14/60) prehospital intubation did not use monitoring in the prehospital setting. With bag volumes in excess of 1,200 mL, uncontrolled bag ventilation can easily lead to inadvertent hyperventilation. In fact, researchers have shown that almost 80% of end-tidal CO₂ values for intubated TBI patients are <30 mm Hg in the field.²⁰ Patients with severe TBI were shown to have decreased mortality when their PaCO₂ was maintained between 30 and 35, 21.2% versus 33.7% by Warner et al. This paper suggests that prehospital monitoring, along with close continued monitoring of arterial blood gases after admission to the hospital will lead to interval decrease in mortality.

Circulation

Evaluation and treatment of circulatory status in the prehospital setting has undergone much change in the past 10 years. The experiences from the Global War on Terror have rapidly changed the way in which we think about prehospital circulation and how we treat the abnormalities in circulation. Evaluation of circulatory status begins with initial evaluation of mental status and inspection for obvious signs of active hemorrhage. Direct pressure and hemostatic dressings can be used for control of hemorrhage; however, large volume extremity hemorrhage may need to be addressed with placement of a tourniquet. A prospective evaluation of tourniquets applied during Operation Iraqi Freedom showed increased survival with tourniquet placement and no subsequent limb loss due to their use.²¹ Passos et al. reviewed the use of emergency tourniquet use in the civilian setting and found that they prevented exsanguination in the setting of both blunt and penetrating extremity trauma.²⁰

Once the circulatory status of the patient has been addressed, sites of rapid compressible exsanguination identified and treated, the decision is made for intravenous access and possible use of intravenous fluid. In 2009 the Eastern Association for the Surgery of Trauma published their practice management guidelines regarding prehospital fluid resuscitation of the injured patient. These guidelines support placement of peripheral IV or intraosseous access only if it does not delay the transport of the patient, as well as small fluid boluses of 250 cc of hypertonic (3% or 7.5%) saline being equivalent to volume resuscitation with 0.9% normal saline or lactated ringers.²² These guidelines also support minimizing fluid resuscitation until hemorrhage is addressed and not resuscitating those patients with penetrating torso trauma. There is, however, data from the Resuscitation Outcomes Consortium (ROC) that resuscitation with hypertonic fluids versus normal saline did not result in improved 28-day survival.²³ The patients were randomized 250 mL boluses of either hypertonic saline (7.5%) versus hypertonic saline per 6% dextran versus 0.9% normal saline. The study was stopped early due to potential safety concern based on increased mortality in the group that received hypertonic saline. As such, current clinical guidelines do not recommend the regular use of hypertonic saline resuscitation in the severely injured patient.

Further evaluation has led researches to push for earlier transfusion of blood product components as in the prehospital setting. Studies from severe combat casualties showed that an aggressive approach to prehospital blood transfusion was associated with large improvement in mortality; however, further randomized studies were necessary.²⁴ Severely injured patients are now receiving blood transfusion in the civilian setting while en route to facilitate early hemostatic resuscitation and prevention of coagulopathy complications. Brown and colleagues conducted a retrospective, case-controlled analysis of patients who received prehospital packed red blood cells (240 patients) against those who did not

(480 patients).²⁵ Their study showed an increased likelihood of 24-hour survival, lower odds of shock, and lower overall 24-hour blood transfused. A subsequent paper from these investigators evaluated over 2,000 blunt trauma patients arrived at one of eight subject institutions within 2 hours of injury.²⁶ Of the 2007 patients, 50 (3.5%) received blood in the prehospital setting, and they were compared to controls who did not. Those patients who received prehospital blood had a 95% reduction in the odds of 24-hour mortality, 64% reduction in 30-day mortality, and an 88% reduction in the incidence of trauma-induced coagulopathy.

In patients without evidence of hemorrhage or in prehospital settings where blood and blood products are not available, numerous choices of fluid are available. However, most fluid options are actually poor choices for resuscitation of injured patients. Normal saline (0.9% sodium chloride) has an average pH of 5.5, with a sodium and chloride concentration of 154 mEq/L. Normal saline is often preferred as a universal solution for prehospital settings as it is “compatible with blood,” contains no potassium, and is cheap to carry; with a low overall cost and extended shelf life. Lactated Ringer’s, initially developed to support organs in the lab (because of calcium content) and later championed for treating cholera, has only a slightly better physiologic profile. Lactated Ringer’s gives the clinician a better average pH of 6.5, with lower sodium (130 mEq/L) and chloride content (109). The optimal fluid, however, is Plasmalyte®/Normosol® which has an average pH of 7.4 and an electrolyte content that resembles a normal metabolic profile (sodium – 140 mEq/L, potassium – 5.0 mEq/L, chloride – 98 mEq/L, and magnesium – 3.0 mEq/L). In addition to its superior profile, Plasmalyte® is compatible with all blood products and has been shown in a randomized trial to result in improved acid–base status and less hyperchloremia at 24 hours postinjury.²⁷ There is increased interest in the use of plasma as a prehospital fluid, be it conventional or freeze dried, and this is reflected in the ongoing Prehospital Use of Plasma in Traumatic Hemorrhage (PUPTH trial).²⁸ The aim of this study is to compare prehospital resuscitation with plasma versus normal saline in patients who are found to be in shock from either blunt or penetrating mechanisms. While results are pending, hopefully this study will shed more light on the ideal type and amount of prehospital fluid for resuscitation.

TRIAGE

Triage is an active process that takes into account multiple factors with the goal of transporting the patient to the correct trauma center in the shortest amount of time. The Centers for Disease Control and Prevention have published guidelines helping to facilitate proper triage of injured patients since 1999. These guidelines underwent their most recent update in 2011 and use physiologic, anatomic, and the mechanisms of the injury to guide the triage of the patient.²⁹ Changes specific to the 2011 update include lowering GCS for the physiologic criteria, broadening the definition of injuries in the anatomic criteria, and addressing the differences in older adult trauma patients relative to young trauma patients. The implementation of these guidelines is key to preventing both under- and overtriage of the acutely injured patient. Undertriage is the practice of sending an acutely injured patient to a lower than needed tier in the trauma system. This leads to prolongation to definitive care for injuries, multiple transfers to identify the correct level of care, and overall worse care of the patient. Overtriage is transferring a patient to a highest-level trauma system when their injuries do not warrant that level of care. This allocates scarce resources to patients who ultimately do not need them, and as such may prevent those who need that resource appropriately from getting it. In 2011, a review of the triage guidelines from 1999 compared to 2006 showed a statistically significant decrease in the number of patients who were overtriaged when the guidelines were followed appropriately.

A special triage situation occurs when multiple patients are injured. A multicasualty event occurs when a hospital is able to manage the number of casualties with local resources. The majority of level 1 trauma centers are able to take care of a small multicasualty event without significant strain on their work environment. A mass-casualty event exists when the numbers, severity, and diversity of injuries overwhelm the local medical resources. A recent example of a mass-casualty event is the April 15, 2013 bombing of the Boston Marathon. A terrorist attack by two terrorists, bent on causing fear and destruction, deployed two homemade improvised explosive devices (IEDs) near the finish line of the race. Two hundred sixty-four patients sought treatment for injuries from the event; there were three fatalities on scene and numerous patients transferred to the five level 1 trauma centers located in Boston.³⁰ An active onsite triage team was able to identify those patients who needed immediate transfer based on criteria and send them to one of the awaiting hospitals for immediate treatment. Specifically, the Brigham and Women’s Hospital received a total of 31 patients immediately following

the bombing, of which 23 arrived within the first hour.³¹ Of those transported to the Brigham that day, fifteen patients were admitted to the hospital, nine went to the operating room, and none died. Mass-casualty events require coordination at the state and national level, and extensive practice at implementing triage criteria. Interestingly, in 2002 the city of Boston completed a citywide mass-casualty practice event in response to the 9/11 Attack. Some credit for the successful actions that due has been given to the experience gained from this practice and other drills.

ADVANCES AND CONTROVERSIES

Rapid Sequence Intubation Versus Non-RSI

The use of rapid sequence intubation (RSI) in the prehospital setting is one that engenders much discussion in the prehospital setting. A standard of care in the inpatient setting, the use of RSI in the prehospital setting is both supported and refuted by the literature over time. The drugs that are used for RSI, while no one standard is accepted by everyone, include combinations of the following: diazepam, succinylcholine, vecuronium, midazolam, rocuronium, lidocaine, ketamine, and etomidate. Many argue that the complications that are associated with RSI, including the consequences of multiple failed intubation attempts, unnecessary exposure of patients to dangerous procedure, and complications of the medications do not value the implementation of RSI in the prehospital setting.

A 2005 paper published on the use of RSI in the out-of-hospital setting was unable to predict which patients had severe TBI and over half the patients experienced a desaturation during the RSI procedure, while only one-quarter of them were hypoxic before RSI.³² A further study from the United Kingdom showed an incidence of 18.3% for hypoxemia during prehospital RSI and 13% developed hypotension lower than pre-RSI blood pressures.¹⁶ This paper attributes its lower incidence of hypoxemia and hypotension to the fact that in the United Kingdom board certified Physicians perform all the prehospital RSI and intubations, while in the San Diego paper the entire procedure was carried out by EMTs. Using a propensity-adjusted model, investigators showed no statistical difference in mortality between prehospital intubations with and without RSI. Further randomized, prospective trials are necessary to prove a benefit to prehospital RSI.

Aggressive Fluids Versus Permissive Hypotension

The concept of permissive hypotension involves keeping the blood pressure low enough to avoid exsanguination while maintaining perfusion of end organs.³³ It is an integral part of the new Damage Control Resuscitation protocols that are being implemented; however, its root goes as far back as World War I. The work of Walter Cannon and John Fraser while serving with the Harvard Medical Unit in France involved the observation that artificial elevations in blood pressure may overcome the clot preventing further hemorrhage, and the patient will lose sorely needed blood.³⁴ Fast forward to 1994 when the plenary paper by Bickell et al. showed in a randomized prospective control trial delayed fluid resuscitation in adults with penetrating torso injuries lead to greater survival and overall shorter hospital length of stay.³⁵ These results have been repeated in further subsequent studies by other authors showing no benefit to early aggressive resuscitation, especially to supernormal levels. Finally, Holcomb et al. in 2007 published the plenary paper on damage control resuscitation outlining the two important principles of resuscitating to a systolic blood pressure no greater than 90 and using thawed plasma in a 1:1 or 1:2 ratio with PRBC to restore intravascular volume.³⁶

The concept of permissive hypotension is directly contradictory to the guidelines found in the ATLS manual that advocate for 2 L of crystalloid resuscitation early in those patients manifesting signs of shock. However, a recent multicenter, randomized study by the ROC suggests that a restrictive strategy is warranted in blunt trauma patients as well.³⁷ The investigators randomized hypotensive trauma patients to receive small boluses of fluid (250 mL) if they had no radial pulse or a systolic blood pressure lower than 70 mm Hg or to receive the standard 2-L fluid bolus and additional fluid needed to maintain a systolic of 110 mm Hg or greater. Patients in the hypotensive resuscitation group (fluid for systolic <70 mm Hg) had a lower 24-hour mortality compared to standard resuscitation group (3% vs. 18%).

Schreiber et al. conducted a randomized prehospital trial placing patients into either of two groups: (1) standard resuscitation patients who received 2 L of crystalloid initially and fluid as needed to maintain a systolic blood pressure of 110 mm Hg or greater, or (2) controlled resuscitation patients who received 250 mL of fluid if they had no radial pulse or an SBP lower than 70 mm Hg, with additional

250-mL boluses to maintain a radial pulse or SBP of 70 mm Hg or greater. The controlled resuscitation group received 1 L less of fluid, had less deaths (5% vs. 15%) at 24 hours after admission, and among patients with blunt abdominal trauma 24-hour mortality was 3% versus 18%, all statistically significant. This paper showed that controlled resuscitation in the out-of-hospital setting may offer an early survival advantage to the blunt trauma patient. There was, however, no difference in mortality among patients with penetrating trauma.

2 Further studies are necessary to cement at which level the resuscitation should be stopped; however, we now know that minimal intravenous fluids, tolerating systolic blood pressures in the 75 to 90 mm Hg range, and not resuscitating to supernormal values with crystalloid is the paradigm prehospital trauma workers should follow.

Prehospital Blood Protocols

The lessons from the Global War on Terrorism have changed many paradigms regarding the prehospital care of the acutely injured patient. Some argue that the advent of prehospital blood product transfusion protocols will make the greatest impact on civilian trauma management. Early studies identified the prehospital setting as an ideal place to begin early resuscitation with blood products, as hemorrhage was identified to cause 33% to 56% of the prehospital casualties. In a multicenter study of over 1,400 injured patients with evidence of shock, Brown and colleagues demonstrated an increase in both 24-hour and 30-day survival, as well as less coagulopathy on arrival in those patients receiving prehospital red blood cell (RBC) transfusions.³⁸ Building on this, the Houston group published their aeromedical experience with prehospital plasma and RBC, which began in 2011.³⁹ Similar to the data published from the wars in Iraq and Afghanistan, the investigators noted in their study of almost 1,700 patients that placing RBCs and plasma products in the prehospital setting, allowing for earlier infusion of life-saving products to critically injured patients, was associated with improved early outcomes.

3 The more recent PROPPR trial included patients who received blood transfusion en route and showed that more patients resuscitation in the 1:1:1 group versus 1:1:2 group achieved hemostasis and fewer experienced death due to exsanguination by 24 hours.⁴⁰ This study will hopefully spur further prospective, randomized control trials trying to identify the proper type and amount of blood product resuscitation in the prehospital setting.

ETCO₂ Monitoring

4 The use of end-tidal CO₂ (ETCO₂) as a means for measurement of exhaled CO₂ is the standard found in the operating room and emergency room; however, its use in the prehospital setting was not commonplace 10 years ago. ETCO₂ is a reflection of metabolism, circulation, and ventilation. As technology has advanced, the ease of use and application of ETCO₂ monitoring has become more commonplace. ETCO₂ was first used as a way to confirm placement of endotracheal tubes in the prehospital setting using colorimetric CO₂ detector.⁸ The use of the colorimetric detector in conjunction with auscultation and symmetric chest rise make the likelihood of esophageal intubation near zero. This must be prevented as esophageal intubation rates have been reported as high as 17% to 25% in emergency airway management of nonarrest patients.⁴¹ In-line capnography in the nonintubated patient is key to assessing the adequacy of chest compressions in patients undergoing CPR. ETCO₂ has been shown to correlate linearly with coronary artery perfusion pressure, and hence is a simple and noninvasive method to measure blood flow during CPR and can indicate return of spontaneous circulation. In 2009 a study of out of Harborview Hospital showed that documented ETCO₂ in prehospital intubations did not correlate to ABG PaCO₂, with patients most likely being under ventilated (PaCO₂ >40) 80% of the time and severely underventilated (PaCO₂ >50) 30% of the time.⁴² As such, the use of ETCO₂ is to assess for proper endotracheal intubation as well as ascertain effectiveness of CPR is established, however, its ability to predict PaCO₂ will need further study.

Tourniquet Use in the Field

5 Tourniquet use for injury has documentation as far back as 6 BC in Hindu text for the treatment of a snakebite.⁴³ Over time it has fallen in and out of favor in the prehospital setting, however, experiences during the recent Global War on Terror support its use as far forward as possible in the prehospital setting. In the Vietnam War surgeons recognized that of the casualties killed in the war, 2,590 lives could have been saved with better prehospital care namely tourniquets.²¹ Analysis of the casualties of Operation Gothic Serpent, the 1993 battle fought between U.S. forces and the militias in Somalia,

showed 7% of fatalities resulted from penetrating extremity trauma and that hemorrhage control in the form of tourniquet use should be more widely adopted.⁴³ The current conflict in Iraq and Afghanistan brought out the strongest data supporting the use of prehospital tourniquets. A prospective study of casualties over a 7-month period in 2006 at a combat hospital in Baghdad showed tourniquet application with the absence of shock was strongly associated with survival, no amputations resulted solely from tourniquet use, and only four nerve palsies at the level of the tourniquet occurred all of which resolved without issue.²¹ Further papers have gone on to show civilian application of this concept also saves lives and limbs. In 2015, Scholl et al. published a retrospective review of civilian trauma patients admitted with a prehospital tourniquet at nine institutions. Their data show overall mortality and limb amputation rate in statistically similarly injured patients was less than that seen in military data previously documented. A final, more fatal, type of hemorrhage is junctional hemorrhage defined as bleeding from the pelvis, groin, perineum, axilla, and neck. These wounds were seen extensively in the Global War on Terrorism as the use of IED increased. Holcomb et al. reviewed preventable causes of death in U.S. Special Forces Soldiers in 2007 and found that junctional or noncompressible trauma was implicated in 47% of deaths.⁴⁴ A future place for research, the junctional tourniquet has shown in healthy volunteers to occlude blood flow to the lower extremity.⁴⁵ While these experiences are mainly from combat environments, application to the civilian field has been successfully implemented.⁴⁶ A paper out of the trauma group at USC showed that prehospital use of tourniquet, be it Combat Application Tourniquet, field expedient tourniquet, or pneumatic tourniquet placed in the emergency room, is associated with no increased rate of complications.⁴⁷ Of note from this study, only 50.6% of the tourniquets were placed in the prehospital setting, leading to further question as to whether or not full implementation of prehospital tourniquets would lead to further success in preventing mortality and decreasing complications from traumatic extremity injuries. A subsequent multi-institutional retrospective analysis of prehospital tourniquet use showed lower overall mortality and limb amputation rates when compared to historical combat data.⁴⁸ This paper showed that extrapolation of military data, as well as practices, to the civilian trauma patient leads to increased survival and limb salvation.

Resuscitative Endovascular Balloon Occlusion of Aorta

Resuscitative endovascular balloon occlusion of aorta (REBOA) is a balloon placed via the femoral artery to occlude the aorta and prevent life-threatening hemorrhage (Fig. 20-1). While the technology is new, the idea is not as it is described in an article in the journal *Surgery* in 1954 for controlling intra-abdominal hemorrhage. Multiple animal studies have shown that REBOA is superior to emergency thoracotomy with aortic clamping to control hemorrhagic shock in the porcine model.⁴⁹ Control of hemorrhage far forward in the military combat environment is the goal of the REBOA. A retrospective analysis of UK combat casualties, 18.5% had an indication for REBOA when reviewing their injuries.⁵⁰ While it is rapidly gaining popularity as a substitute for resuscitative thoracotomy, it is probably best suited for quickly controlling pelvic hemorrhage (before the patient has lost pulses) prior to embolization and interventional radiology availability. Research is now being produced that shows a benefit to REBOA use for hemorrhage control. Brenner et al. published a series of six cases in 2013 that outlined the successful implementation for hemorrhage control of REBOA.⁵¹ Successful implementation of REBOA in these six cases showed that endovascular aortic occlusion supports myocardial and cerebral perfusion until resuscitation can be initiated and hemostasis obtained, the same goals of aortic cross clamping in a markedly less invasive manner. Further research published in 2015 compared the outcomes of REBOA versus resuscitative thoracotomy for noncompressible truncal hemorrhage. In clinically similar groups, the REBOA group had fewer early deaths, improved overall survival (37.5% vs. 9.7%, $p = 0.003$) with less morbidity than the resuscitative thoracotomy group.⁵² While this took place in only two centers with advanced skills with REBOA, it is feasible that continued training in endovascular skills during both the training and attending years may lead to greater implementation of this skill. The Japanese have published a retrospective review of their experience with the safety and feasibility of REBOA for trauma in 2014.⁵³ Their data show that REBOA was feasible for trauma resuscitation, however, there was an increased risk of lower limb ischemia and possible amputation that occurred in 12.5% of their patients. New technologic advances producing small sheaths and smaller balloons may eliminate the need to close an arteriotomy required of larger sheaths and thus decrease this risk. Further forward management of REBOA in the field environment may be on the horizon, however, for now its implementation to control traumatic hemorrhage is still in its infancy and the risk-benefit of placing these in the most skilled hands (much less in undertrained personnel or in the

prehospital setting) has not been determined.⁵⁴

Figure 20-1. Performance of REBOA. Steps of Insertion:

1. Use the percutaneous entry thin wall needle to access the common femoral artery via cutdown, percutaneous access, or wired exchange of existing arterial line (A).
2. Insert the Rosen guide wire (0.035) through the needle, then remove the needle (B).
3. Open the CODA catheter kit: dilate with the gray 10-Fr then the 12-Fr dilator (C).
4. Through the 12-Fr dilator, exchange the 0.035 guidewire for the Amplatz super stiff guidewire.
5. Dilate with the 14-Fr dilator and then assemble the introducer sheath by placing the 14-Fr dilator through the sheath (like a Cordis). Insert the dilator/sheath unit over the guidewire. Place the sheath to a premeasured distance (arterial puncture to umbilicus) then remove the dilator but not the

- guidewire (D).
6. Open CODA balloon (yellow) and remove black tip. *Do NOT test balloon* (E).
 7. Insert balloon catheter to premeasured distance + 10 cm.
 8. Place three-way stopcock (packaged separately in balloon kit) to the end of the balloon catheter.
 9. Gently inflate balloon through the sideport until loss of contralateral femoral pulse (can confirm with Doppler US). Do not exceed 40 mL (can use air, saline, or 50% contrast diluted with saline). (E).
 10. Secure catheter to the patient and document positioning with KUB or fluoroscopy.
-

CONCLUSION

Prehospital trauma care is a constantly evolving field. Much of our advances from recent military conflicts are being rapidly implemented in the civilian prehospital setting. Further research and developments are necessary to continue the previous success seen in saving the critically injured trauma patient.

Chapter 21

Head Trauma

Phiroz E. Tarapore, Geoffrey T. Manley, and Randall M. Chesnut

Key Points

- 1 Care must be taken to avoid hypotension and hypoxia, as these cause secondary injury.
 - 2 In the setting of hypotension, ample volume resuscitation is the first line of therapy.
 - 3 In the absence of intracranial hypertension, ventilation should be maintained with a target PaCO₂ > 35 mm Hg.
 - 4 Hemoglobin should be maintained at or above 7 g/dL.
 - 5 Traumatic CSF leak should be observed initially, without antibiotic prophylaxis. Persistent leak may require temporary CSF diversion and, if that fails, operative management.
-

INTRODUCTION

In the field of trauma, other than for exsanguinating injuries, traumatic brain injury (TBI) is the injury most commonly responsible for mortality, accounting for about half of deaths at the scene. In the United States alone, the annual incidence is 2.5 million, and TBI results in over 52,000 deaths per year.¹ The injuries are generally blunt, occurring most frequently in motor vehicle crashes (MVCs). As many as two-thirds of all MVC victims sustain some degree of brain injury. The incidence of TBI is also increasing globally, driven mainly by the increasing use of automobiles.

These data are generally applicable to children as well. Although the mechanisms vary, head injuries are the major cause of morbidity and mortality in childhood trauma victims, accounting for an annual mortality rate of 1 per 1,000 in this age group.² Falls are the leading cause of TBI in those under age 14 years.

Interestingly, falls are also the leading cause of TBI in those over age 65 years. With the aging of the baby-boomer generation, a new spectrum of brain injury is blossoming. For persons 65 years and older, TBI-related hospital admissions increased more than 50% between the periods of 2001–2002 and 2009–2010.³ These patients have less inherent neurologic plasticity, limiting their recovery potential. Furthermore, they tend to have significant comorbidities and may be on one or more anticoagulants. The management of these patients is often different from that which is optimal for the younger population.

In patients with TBI, extracranial trauma is present in over half of cases. In these polytrauma patients, the best predictor of outcome is severity of the TBI.⁴ It is therefore critical for a polytrauma patient to be expeditiously transported to a trauma center that can offer the multidisciplinary specialized care that is required. Patients with severe TBI, in particular, should be managed at a center with immediate CT capability, neurosurgical care, and ICP monitoring capability.⁵ For these patients, direct transport to a level I or level II is associated with up to a 50% decrease in mortality.⁶

PATHOPHYSIOLOGY

Traumatic injury to the brain involves a primary brain injury that occurs at impact and leads to disruption of brain substance and blood vessels. In addition, secondary brain injury may result from hypoxia, hypotension, hyperventilation, pyrexia, the effects of increased intracranial pressure (ICP), and altered cellular biochemical processes that are often ongoing long after the primary insult.

Primary Injury

Energy transfer to the head causes direct disruption of neurons, glia cells, and microvasculature localized at the area of impact. As the brain rebounds within the skull, it is also vulnerable to impact

with the opposite inner table. Therefore, countercoup injury to the contralateral brain is relatively common, in some cases being more severe than the damage at the primary impact site.

Particularly when the mechanism includes rotational forces, head trauma can result in widespread disruption of white matter axons throughout the brain, producing the condition termed *diffuse axonal injury* (DAI). Such injuries often damage a large number of widely distributed neurologic systems. When such injuries involve ascending pathways in both hemispheres or in the brainstem, the result is a depressed level of consciousness. The brain is also subject to torsion injury resulting from rotation around the fixed brainstem. This type of injury can damage the reticular activating system, producing unconsciousness.

Intracranial hemorrhage can take many forms. Direct laceration of epidural arteries from impact fractures or bleeding from fracture lines produces epidural hematomas, which damage the brain by compression. Disruption of bridging subdural veins and bleeding from cortical tissue damage produces a subdural hematoma, which is generally associated with disruption of underlying brain tissue. Intracerebral contusions, lacerations, and hematomas are caused by direct tissue disruption with associated vascular injury, producing neuronal damage and intraparenchymal bleeding.

Penetrating injury damages the brain through tissue injury caused directly by the projectile and, in the case of projectiles with relatively high velocity, result in disruption of neural tissue at a greater distance from the track via cavitation injury. In survivors, the extent and degree of the cavitation injury (related linearly to the mass and in a squared fashion to the velocity of the projectile) are often the primary determinant of outcome. Another source of morbidity is vascular injury, producing aneurysms, pseudoaneurysms, and other vascular anomalies that may present immediately or be delayed.

Whether a projectile or direct impact causes contusion, subdural hematoma, epidural hematoma, or DAI, currently little can be done therapeutically to change the magnitude or location of the primary injury once it has occurred. As such, most of our present care focus is on secondary injuries.

Secondary Injury

Once a primary brain injury has occurred, it sets off a variety of pathologic processes including neurotransmitter release, gene activation, mitochondrial dysfunction, and neuroinflammatory responses over the course of hours and days. These cascades, along with intracranial hypertension and cerebral ischemia, can cause secondary brain injury. The prevention of these secondary injuries is the goal of both medical and surgical management of TBI.

Biochemical and Genomic Processes

Primary tissue injury initiates a variety of biochemical processes, including free radical-mediated lipid peroxidation, excitotoxic “superactivation” of glutamate-aspartate neurotransmitter systems, and alterations in membrane receptor and ionic channel characteristics, among others. A variety of genomic processes are also activated, including apoptotic cell death. These processes can proceed for significant periods of time following primary injury and often are self-sustaining. The goal of the numerous clinical trials involving treatment of patients with brain trauma with various pharmacologic agents is to determine the means by which these processes may be attenuated or reversed. Unfortunately, to date, no clinically useful tools have been obtained from such research.

Cerebral Hypoperfusion and Hypoxia

1 The most dangerous secondary injury processes that occur following brain injury are systemic hypotension and hypoxia. Hypotension is the number one treatable determinant of severe head injury. A single episode of systolic blood pressure less than 90 mm Hg occurring during the period from injury through resuscitation doubles the mortality and significantly increases the morbidity of any given brain injury.^{7,8} Furthermore, an early hypotensive episode strongly increases the probability of later intracranial hypertension. For these reasons, rapid and complete restoration of blood pressure is the most important goal in the resuscitation of the brain-injured patient.

Hypoxia (apnea or cyanosis in the field or a partial pressure of arterial oxygen [PaO₂] 60 mm Hg) is also an independent predictor of poor outcome.⁷⁻⁹ The frequency and magnitude of hypoxia have been notably decreased by modern airway management techniques, particularly endotracheal intubation and assisted ventilation, in addition to ensuring adequate oxygen-carrying capacity through the avoidance of anemia. Recent studies suggest that intubation is safest in the hospital setting, and most emergency medical systems will not intubate patients in the field so long as they are ventilating and oxygenating adequately and transport time to the hospital is short.¹⁰⁻¹³

Cerebral tissue oxygen tension (PBtO₂) can be measured directly using implantable Clark electrodes. This makes it possible to follow the partial pressure of oxygen in the brain tissue. Although absolute thresholds have not been rigorously determined, values above 15 to 20 mm Hg are generally considered adequate and values below 5 mm Hg are associated with increasingly poor outcome in a duration-dependent fashion.^{14,15} The major limitation of this system is the focal nature of its monitoring – it offers a single value relevant to a small volume of brain that is usually outside the region of injury. Although there is theoretical attractiveness to monitoring at the border of focal injuries (the “penumbra”), most monitoring is performed within normal brain. With the addition of a jugular venous oxygen saturation monitor (JVO₂), it becomes possible to measure global cerebral oxygen extraction and distinguish hypermetabolic, high extraction states from hyperemic, low extraction states. Thus these two oxygen monitoring tools are complimentary.

Intracranial Hypertension

ICP is a function of the aggregate volumes of brain, cerebrospinal fluid (CSF), and blood within the fixed intracranial compartment. Mild or slow expansion of one or two of these compartments can be buffered by compensatory decreases in either the CSF or blood compartments (into the spinal subarachnoid space or the venous sinuses, respectively). When this buffering capacity is exceeded, the compliance of the brain is compromised and small additional increases in any intracranial compartmental volume will produce marked elevations in ICP.

Intracranial hypertension is considered deleterious via two somewhat separable mechanisms: herniation and ischemia. Herniation occurs when a pressure gradient exists across an incomplete barrier, such as the tentorium, falx cerebri, or foramen magnum. It is deleterious because of the tissue damage that occurs and direct compression of adjacent vessels. Transtentorial herniation, the most recognized form, is manifest by anisocoria, motor posturing, autonomic disturbances, and death. The specter of herniation is the major determinant of the absolute threshold of ICP management, which is generally accepted as 20 to 25 mm Hg (although this range has not been well determined empirically).

The second deleterious aspect of intracranial hypertension is elevated resistance to cerebral blood flow (CBF), resulting in or exacerbating cerebral ischemia. This resistance can be very roughly approximated by cerebral perfusion pressure (CPP), which is defined as the difference between mean arterial blood pressure and ICP:

$$\text{CPP} = \text{mean arterial pressure} - \text{ICP}$$

Under normal circumstances, cerebral pressure autoregulation maintains CBF stable over a wide range of CPP (approximately 50 to 150 mm Hg) (Fig. 21-1). Following injury to the brain, this autoregulation is generally disrupted. This disruption can be complete, resulting in a pressure-passive system.¹⁶ Failure of autoregulation is associated with worse outcome in patients with TBI.¹⁷ More frequently, the disruption is incomplete, characterized by a normal sigmoid shape but with abnormal elevation of the lower breakpoint above the normal value of 50 mm Hg (sigmoid dashed line). A probable consequence of this disruption is that a CPP that is satisfactory for uninjured patients may be associated with a lower CBF following head trauma (range of hypoperfusion).

In a pressure-passive system, cerebral blood volume (CBV) will increase in proportion to CPP. In such an instance, the goal is to keep the CPP just above the level of cerebral ischemia, thereby minimizing iatrogenic intracranial hypertension driven by increased CBV. In the situation of incomplete disruption, the goal is to keep CPP within the range of autoregulation, because this not only avoids ischemia but also may decrease ICP if autoregulatory vasoconstriction in response to increased CPP serves to decrease CBV.

Keeping the CPP in a physiologically normal range of 50 to 70 mm Hg is the recommendation of the most recent revision of the Guidelines for the Management of Severe Brain Injury.^{18,19} A CPP less than 50 mm Hg should be avoided. Driving CPP greater than 70 mm Hg with fluids and vasopressors should also be avoided because of the risk of adult respiratory distress syndrome.²⁰ The CPP target for an individual patient depends on the status of cerebral autoregulation and determination of the optimal CPP can be facilitated with neuromonitoring. Furthermore, since CPP is calculated from MAP – ICP, a low CPP may be a result of low MAP and/or elevated ICP. Interventions taken to address low CPP must therefore be targeted at the relevant component: blood pressure support in case of low MAP, and ICP reduction for elevated ICP.

Figure 21-1. Cerebral pressure autoregulation. The normal relationship is indicated by the *solid line* with autoregulatory breakpoints at 50 and 150 mm Hg. Two disrupted states are also diagrammed. Complete loss of autoregulation (*straight dashed line B*) results in a pressure-passive system wherein cerebral blood flow (CBF) (and cerebral blood volume [CBV]) increases linearly with cerebral perfusion pressure (CPP). The more common form of disruption is indicated by the sigmoid (*dashed line A*) where the major alteration is a right shift in the lower breakpoint. The *circles* at the top of the figure represent the diameters of the resistance vessels in the normal situation. The area of the circles represents CBV. Shifting this relationship to the right by 30 mm Hg would represent the partially disrupted state. (© R.M. Chesnut, MD, reproduced with permission.)

CLINICAL ASSESSMENT

The objectives during early clinical assessment of the patient with head injury are multiple and must be accomplished simultaneously. These include establishing adequate oxygenation, ventilation, and circulatory stability and evaluating the extent of brain injury while treating ICP elevations. Although some evidence indicates that systemic hypotension may infrequently be the result of a head injury, always initially presume that hypotension in a trauma patient is the result of hypovolemia. It is a significant error to withhold volume resuscitation in a misdirected effort to control cerebral edema.

During initial assessment, mental status changes cannot be presumed to be the result of drugs or alcohol, although routine toxicology screening is appropriate. It should be presumed that any change in mental status or the neurologic examination in general, or any evidence of herniation (e.g., anisocoria), suggests an expanding intracranial mass lesion. Under such circumstances, therapeutic ICP reduction becomes the first priority and diagnostic imaging or surgical decompression must be accomplished emergently.

Do not assume that apparent neurologic unresponsiveness represents a lack of sensitivity to pain. Noxious stimuli, such as placement of urinary drainage catheters, nasogastric tubes, or IV catheters, can precipitate ICP peaks during resuscitation. These procedures should be done quickly and efficiently, optimally after sedation. Endotracheal intubation is particularly likely to induce herniation in borderline cases. Whenever practical, consider premedication with analgesics, sedatives, or IV or endotracheal lidocaine before airway instrumentation.

With regard to the brain injury, several critical assessments are necessary and should be precisely recorded because trends are at least as important as any single observation. The three key parameters are level of consciousness, pupillary reflexes and size, and the motor examination.

Glasgow Coma Scale

The single most important assessment for a patient with head injury is to evaluate the level of consciousness. In this regard, the Glasgow Coma Scale (GCS) has become an international standard that is easily, rapidly, and reliably obtained ([Algorithm 21-1](#)).²¹ Components of the GCS include assessment of eye opening (E), verbal response (V), and motor response (M). The Guidelines for the Prehospital Care of Severe Brain Injury support the use of the GCS for all prehospital care providers.²² Special training has been developed by the Brain Trauma Foundation to optimize its accuracy (<http://www.braintrauma.org/>).

For individual patients, it is recommended that all three components be reported separately (e.g., E4V5M6) instead of a sum score (e.g., GCS = 15).²³ The derived sum score is more relevant for comparisons at the group level, and for classification and prognosis. For triage purposes, patients can be stratified using their GCS scores into those with severe injuries (GCS ≤ 8), moderate injuries (GCS 9 to 12), or mild injuries (GCS ≥ 13 ; see [Algorithm 21-1](#)).

Assessment requires either a spontaneous response or response following application of a stimulus. At more severely disturbed levels of consciousness, the motor score has better discrimination, but in milder injuries the eye and verbal components are more relevant. Thus each component of the scale provides complementary information. Strengths of the GCS are that it covers a broad spectrum of disorders of consciousness, is widely applicable, and offers an important tool for monitoring changes in the level of consciousness. Standardized approaches to both its assessment and its reporting are required in order to be able to compare evaluations over time or when communicating with other healthcare professionals. Spontaneous responses are first observed without stimulating the patient in any way. First verbal stimuli are applied, such as asking a patient to obey commands and at the same time observing whether, for example, an eye opening occurs. If a patient is not responsive, a stimulus is applied to elicit a response. The location of the stimulus (central or peripheral) should be standardized and used consistently. To describe the motor response, only the reaction of the arms should be observed, not the legs.²⁴

Algorithm 21-1. Glasgow Coma Scale (GCS) triage guide for initial evaluation of head injury. For the motor scale, the best response for any limb is recorded.

If a GCS component is untestable due to intubation, sedation, or other confounder, the reason for this should be recorded (e.g., E1VTM2, with “T” indicating “intubated” and not a testable verbal component). A score of “1” should not be assigned because differentiation between a “true 1” and an untestable component is relevant.

Pupils

Pupillary asymmetry, dilation, or loss of light reflex in an unconscious patient usually reflects herniation because of the mass effect from intracranial hemorrhage ipsilateral to the dilated pupil. The probability of an intracranial mass lesion can be roughly approximated given the degree of anisocoria (1 mm or 3 mm), the mechanism of injury (MVC), and age ([Fig. 21-2](#)).²¹ Occasionally, pupillary signs may indicate direct second or third nerve injury or trauma to the globe, but this must always be a diagnosis of exclusion. An unequal and nonreactive pupil is the cardinal sign that herniation is occurring, and rapid lowering of ICP is essential. An ovoid pupil is also ominous and is associated with injuries that result in herniation in approximately 15% to 20% of patients.

Figure 21-2. Estimated percentage chance of an extra-axial intracranial mass lesion greater than 25 mL as a function of degree of

anisocoria, age, and mechanism of injury. Mechanism of injury was defined as motor vehicle accident (MVA) or other mechanism (not MVA). (Reproduced with permission from Chesnut RM, Gattille T, Blunt BA, et al. The localizing value of asymmetry in pupillary size in severe head injury: relation to lesion type and location. *Neurosurgery* 1994;34:840–845.)

Recently, handheld pupillometry has gained acceptance as a method for quantifying pupillary response. Traditionally, the measurement of pupil function has been subjective, using a flashlight and pupil gauge with a qualitative assessment of reactivity, often resulting in poor interrater reliability.²⁵ The currently available devices measure the rate and degree of pupillary contraction and calculates a normalized neurologic pupillary index, or NPi.^{26,27} NPi > 4 is indicative of normal function, while NPi < 4 raises suspicion for pupil contractility dysfunction. It should be noted that, although one etiology of decreased NPi is increased ICP, other causes such as direct cranial nerve III dysfunction or diabetic pupillary paresis must also be considered.

Motor Examination

The motor system is examined for asymmetry, abnormal posturing, or lack of movement. Hemiparesis, paraparesis, or quadriparesis suggests a cervical or thoracolumbar spine fracture with spinal cord injury. Hemiparesis secondary to brainstem herniation from the mass effect may be either ipsilateral or contralateral to the side of the dilated pupil or an intracranial mass lesion.²¹ Hemiparesis may also result from significant brain contusion. In the unconscious patient, a painful stimulus should be used to evaluate motor function. All four extremities should be examined and the results noted, because only the response of the best limb will be reflected in the GCS score.

RADIOGRAPHIC DIAGNOSIS

Neurosurgical evaluation and assessment are initiated as soon as the potential for significant head injury is realized. Prompt radiographic evaluation is essential and CT scanning is the imaging modality of choice for virtually all acute neurologic conditions. Patients with mild head injuries can usually be observed with sequential examinations and radiographic evaluation may be unnecessary unless the results determine whether the patient can be discharged from the hospital. In contrast, however, a cogent argument can be made for the liberal application of CT scanning to even patients with minimal evidence of TBI as a method of making safe, efficient, and economic triage decisions.³⁰ In any instance, evidence of neurologic deterioration or the occurrence of a situation wherein the neurologic examination cannot be followed (e.g., the need for general anesthesia) mandates CT scanning, intraoperative ICP monitoring, or both. General indications for neurologic imaging (generally, CT scanning) are listed in Table 21-1.

Patients with moderate or severe injuries require prompt neurosurgical consultation and rapid radiographic evaluation using the CT scanner. Hemodynamically stable patients with significant neurologic deterioration should go to the CT scanner immediately following ATLS resuscitation. In hemodynamically unstable patients who require immediate surgical intervention to sustain intravascular volume, lifesaving exploratory thoracotomy or laparotomy must take precedence. In such cases, it is a mistake to delay further investigation of the intracranial compartment pending the end of the case and transport to the CT scanner. A number of methods can be employed to evaluate the intracranial compartment during such lifesaving, extracranial surgery, including insertion of an ICP monitor or ventriculostomy (with air ventriculography, if deemed necessary), transcranial Doppler evaluation, or even placement of exploratory burr holes in the instance of herniation. For this reason, neurosurgical consultation should be initiated on arrival in theater rather than at the finish of the case.

Table 21-1 Indications For Neurologic Imaging

- Suspected skull penetration by a foreign body
- Discharge of cerebrospinal fluid (CSF), blood, or both from the nose
- Hemotympanum or discharge of blood or CSF from the ear
- Prolonged unconsciousness
- Altered state of consciousness at the time of examination
- Focal neurologic signs or symptoms
- Any situation precluding proper surveillance
- Head injury plus additional trauma
- Possible head injury in the presence of additional pathologic findings, such as stroke
- Head injury with alcohol or drug intoxication

At the other end of the spectrum, in cases where there is an obvious surgical brain injury, the choice and timing of diagnostic systemic maneuvers should be subject to modification. Such patients should be transported directly to theater and examinations such as focused assessment with sonography in trauma (FAST) or diagnostic peritoneal lavage performed as the patient is being prepped for craniotomy. In such instances, obviously, early communication between the trauma surgery and neurosurgery departments is critical.

The spine should be cleared radiographically or immobilized and protected in every patient with a severe head injury. Although only 13% of patients with severe head injuries have spinal cord injuries, the potentially devastating consequences of an overlooked spine injury require constant vigilance.

Plain Skull Radiographs

With the routine availability of 24-hour CT scanning capabilities, plain skull radiography has largely become obsolete in TBI. The likelihood of a surgical intracranial hematoma is strongly correlated with the presence or absence of a skull fracture if the neurologic examination is factored in.³¹ Nevertheless, the superiority of CT imaging in all aspects of evaluating TBI has relegated the use of skull films to unusual circumstances.

Computed Tomography

The CT finding that correlates most highly with intracranial hypertension is compression or obliteration of the basilar cisterns (Fig. 21-3). Not only does this finding portend a stormy ICP course, but also the primary predictor of outcome in patients with this CT picture is the peak level of intracranial hypertension occurring during the first 72 hours.^{32,33} When cisternal compression is paired with a midline shift of more than 5 mm, the prognosis is even more ominous. ICP monitoring should be immediately initiated in any patient with cisternal compression and intracranial hypertension should be vigorously treated. Such patients, particularly those with minimal evidence of contusions, die primarily from secondary brain insults, which implies that they are potentially salvageable.

Figure 21-3. A computed tomography scan that is highly predictive of intracranial hypertension. The basilar cisterns are obliterated and the sulci are flattened.

Acute epidural hematomas correlate well with skull fractures. The most common association is a linear, nondisplaced fracture in the temporoparietal region, crossing the middle meningeal artery. The classic clinical course involving a lucid interval following a brief loss of consciousness with subsequent suspicion must remain high. The typical CT appearance is a high- or mixed-density concave extra-axial hematoma with smooth borders (Fig. 21-4).

Figure 21-4. Typical computed tomography scan appearance of mixed-density, lens-shaped, acute epidural hematoma with mass effect.

Acute subdural hematomas occur over the convexity of the brain. The hematoma may evolve from rupture of bridging cortical veins or bleeding from the underlying parenchymal injury, the latter being a common source. It is this subjacent tissue damage that generally determines the neurologic outcome of patients not succumbing to intracranial hypertension. On CT scan, a subdural hematoma appears as an extra-axial high- or mixed-density crescentic mass that spreads out over the hemisphere, following the cortical irregularities (Fig. 21-5). The midline shift may be out of proportion to the size of the hematoma because of the contributing mass effect from an underlying brain contusion or hemispheric swelling.

Intracerebral hemorrhage and cerebral contusion are common after trauma and are readily visualized with CT scanning. Brain contusion appears as a focal, heterogeneous density with hemorrhage interspersed with injured tissue (Fig. 21-6). Intracerebral hematomas are generally more homogeneous in their high-density appearance. Both of these lesions tend to “blossom” over time because of some continued hemorrhage and the development of edema. It is important, therefore, to closely observe and monitor the ICP of such patients because significant and hazardous mass effect may evolve, requiring surgical extirpation.

With temporal or deep frontal contusions, late deterioration may occur, generally because of progressive edema development. The peak of such deterioration appears to be around 1 week, although cases have occurred as late as 10 to 14 days. Most of these patients will complain of severe or increasing headache or their CT images will show progressive edema formation. As such, a high index of suspicion must be accompanied by liberal use of follow-up CT imaging and, in particular, not dropping the level of surveillance until both the clinical situation and the CT appearance are stable. In the instance of such lesions showing progressive mass effect, the insertion of an ICP monitor may be considered, even in a patient with a relatively high GCS score.

Figure 21-5. Usual computed tomography scan appearance of a crescent-shaped, high-density blood collection conforming to the contour of the cerebral hemisphere in a subdural hematoma.

Figure 21-6. Contusion and associated intracerebral hematoma in the frontotemporal area.

The typical CT appearance of subarachnoid hemorrhage is a layer of blood over the cerebral cortex, layering over the tentorium and commonly filling the basal cisterns. Cerebral edema appears as areas of decreased density, which may be either focal or diffuse. Posttraumatic edema formation generally takes hours to days to develop unless compounded by hypoxia or hypotension. The “swollen brain” commonly seen in the setting of trauma may be caused by edema or increased CBV (unclothed, intravascular blood is low density). DAI, typical of acute acceleration–deceleration injury, appears on CT scan as small areas of focal hemorrhage in the brainstem, thalamus or deep nuclear region, corpus callosum, and hemispheric white matter and may be accompanied by cerebral swelling. Finally, gunshot wounds or other penetrating injuries can be evaluated with CT scanning to allow accurate preoperative assessment of the anatomic injury for prognostic and therapeutic planning purposes.

One significant issue of recent origin is the “blossoming” or appearance of new lesions subsequent to CT images obtained at very short intervals following injury. Most of the “classic” TBI studies presented initial CT data from studies done hours following trauma. With improved prehospital transport and the ready availability of CT imaging, many initial studies are now performed 15 to 30 minutes after injury. As a result of such ultra-early CT scanning, there is now a risk of missing significant intracranial lesions

by obtaining imaging before their appearance or during an early phase of their evolution. For this reason, in any patient with moderate or severe TBI, intracranial hypertension, or anticoagulation/antiplatelets, we routinely obtain an early follow-up CT image at 4 to 6 hours after admission. In patients with mild TBI who have a stable neurologic examination and none of the aforementioned risk factors, routine repeat head CT rarely changes management and may be skipped.²⁸⁻³¹

It should be noted that absence of CT findings in a patient with a history of TBI does rule out a TBI. Recent data suggest that a significant number of patients seen at a level I trauma center with a negative CT will have pathologic findings with 3T MRI imaging.³² Advanced MRI techniques, such as diffusion tensor imaging and functional MRI hold great promise for improved diagnosis and prognosis, especially in mild TBI/concussion.³³

Ancillary Imaging

As noted earlier, there is a significant association between TBI and injury to the axial skeleton, particularly to the cervical spine. In addition, particularly when associated with basilar skull fractures or facial fractures, TBI suggests the possibility of damage to the major arteries of the neck. As such, particular attention should be given to careful radiographic clearance of the spine and consideration of studies such as CT angiography of the great vessels rostral to the aortic arch.

MANAGEMENT

Evidence-based Medicine and the Management of Traumatic Brain Injury

Wherever possible, the recommendations in this text are evidence based. For details, the reader is referred to the source documents.

The publication of the first edition of the Guidelines for the Management of Severe Brain Injury in 1996 represented a significant step in standardizing the management of TBI based on published, peer-reviewed literature.²² This document represents the application of a strict evidence-based process to 14 topics relevant to TBI care. Following an exhaustive, explicitly defined literature search covering each topic, the recovered literature was carefully classified along a three-point continuum of scientific rigor. As such, each article was ranked as class I, class II, or class III and the analysis of the scientific basis of each topic was predicated on the most scientifically rigorous (highest literature class) reports available. This process produced a set of standards, guidelines, and options for treatment where **standards** (based on class I evidence) represent principles with a high degree of clinical certainty, **guidelines** (based on class II evidence) reflect principles with a moderate degree of clinical certainty, and **options** (based on class III evidence) reflect principles for which unclear clinical certainty exists. By specifically defining the scientific foundation on TBI management issues, the Guidelines for the Management of Severe Brain Injury provided an unbiased reference focused on facilitating scientific management of TBI.

Since the initial publication of the Guidelines for the Management of Severe Brain Injury, it has undergone updating and revision^{10,11} encompassing more recently published data and revising earlier practice recommendations where indicated as well as expanding the scope of covered topics. The same evidence-based process has also been applied in the generation of other sets of brain injury guidelines. The Guidelines for the Prehospital Management of Traumatic Brain Injury were published in 2002,²⁰ spawning the training efforts mentioned previously. In 2001, the Guidelines for the Management of Penetrating Brain Injury (PBI) were published.²³ The Guidelines for the Management of Pediatric Brain Injury were published in 2003.¹⁸ The Guidelines for the Surgical Management of Traumatic Brain Injury were published in 2001.²⁴ The third edition of the Guidelines were published in 2007³⁴ and work on the fourth edition is now underway.

General Considerations

Although there is no present technology for its quantification before the insertion of an ICP monitoring device, early intracranial hypertension may certainly exert a detrimental influence on outcome. Not only do all treatment modalities for intracranial hypertension have serious potential complications, but also many of them can directly interfere with resuscitation procedures (e.g., use of osmotic diuretics). The efficacy of successful systemic resuscitation in improving the likelihood of survival from trauma in general is well accepted. In addition, the acknowledged negative influence of secondary insults (e.g., hypotension and hypoxia) on outcome from severe head injury renders systemic resuscitation essential.

Therefore, all treatment must be consistent with optimal systemic resuscitation.

The composition and volume of the IV fluids used to resuscitate patients with head injuries should be selected with the purpose of restoring intravascular blood volume. Although the widely disseminated but scientifically unsupported adage of “keeping TBI patients dry” has now been discarded, the concept of restricting free water remains desirable. As such, isotonic crystalloid solution in the form of 0.9% normal saline (NS) is preferable to lactated Ringer solution as a resuscitation fluid for TBI.³⁵ For some time, a growing body of indirect scientific support appeared to support the use of 250 mL of 7.5% hypertonic saline as the first resuscitation fluid in TBI victims. However, a recent randomized controlled trial from Australia has suggested that this may not be of benefit under optimal resuscitation conditions.²⁸

The endpoints of resuscitation do not change depending on the presence or absence of a head injury. Blood volume should be normal, with an appropriate blood pressure and central venous pressure, adequate urine output and peripheral perfusion, and progressive improvement of any base deficit. The systolic blood pressure should never be allowed to drop below 90 mm Hg. Some evidence indicates an advantage to targeting a mean arterial pressure of 80 to 90 mm Hg during resuscitation until ICP monitoring can be initiated. Once ICP is available, a minimal CPP of 60 mm Hg should initially be the goal.

Initial Resuscitation

Resuscitation in the Absence of Clinical Signs of Herniation

2, 3 [Algorithm 21-2](#) is based on the Guidelines for the Management of Severe Brain Injury and the Guidelines for the Prehospital Management of Severe Brain Injury for use by prehospital and initial at-hospital care providers and emergency physicians to guide decision making in resuscitating TBI victims and determining the necessity of ICP-lowering therapy.^{22,34} “Signs of increased ICP” implies pupillary abnormalities, motor posturing, or neurologic deterioration not related to medications. When these signs are not present, mannitol is not given and the goal of ventilation is eucapnia (i.e., no hyperventilation). When signs of herniation are present, the patient is hyperventilated to a PaCO₂ of 30 to 35 mm Hg and mannitol may be given if the patient’s volume status is normal.

[Algorithm 21-3](#) is based on the Guidelines for the Management of Severe Brain Injury for evaluation and treatment of the severe TBI patient from arrival at the trauma center prior to the placement of an ICP monitor.³⁴ As with any trauma patient, the first step is Advanced Trauma Life Support (ATLS) resuscitation. When appropriate, brain-specific therapies are incorporated into the treatment course. Brain-friendly initial ICU management should lead directly to monitoring of ICP.

Elevating the head of the bed (reverse Trendelenburg position in the absence of clearance of the axial skeleton), a standard maneuver to improve cerebral venous outflow and reduce ICP, has also been shown to generally lower the CPP in the absence of adequate volume resuscitation. Because the reduction in CPP may elevate the ICP per se, it is not advised until complete resuscitation has been accomplished.

Algorithm 21-2

Algorithm 21-2. Prehospital evaluation and treatment of a patient with severe traumatic brain injury. “Signs of increased ICP” is the decision point for determining the necessity of intracranial pressure (ICP)-lowering therapy. These signs include pupillary abnormalities, motor posturing, or neurologic deterioration not related to medications. The order of steps is determined by the risk–benefit ratio for individual treatment maneuvers. This algorithm should be viewed as “expert opinion” and used as a framework, which may be useful in guiding an approach to field management of such patients. (© R.M. Chesnut, MD, FCCM, reproduced with permission.)

The confusion and agitation often associated with head injury can increase intracranial hypertension. Therefore, patients with suspected head injury should generally receive sedatives and analgesics whenever possible. Particularly in the TBI patient, the difference between sedation and analgesia should be kept in mind and the two agents titrated specific to their respective indications. Short-acting agents such as propofol are preferable in the interest of following the neurologic examination.

In addition to eliminating any possibility of spontaneous ventilation and mandating complete ventilatory control, pharmacologic relaxation has the undesirable effect of limiting the neurologic examination to the pupils and the CT scan. Its use in the absence of evidence of herniation, therefore, should be limited to situations where sedation and analgesia alone are not sufficient to optimize safe and efficient patient transport and resuscitation.

The “prophylactic” administration of mannitol is not suggested, because of its volume-depleting diuretic effect. In addition, although it is desirable to approximate the lower end of the normal range of PaCO₂ during transport of a patient suspected of having brain injury, the risk of exacerbating early ischemia by vigorous hyperventilation outweighs the questionable benefit in the patient without evidence of herniation. Therefore, ventilation parameters consistent with optimal oxygenation and “normal” ventilation are recommended. The minute ventilation should be targeted at 100 mL/kg per minute until quantitative measurement of end-tidal carbon dioxide (EtCO₂) or PaCO₂ is available. The Guidelines for the Prehospital Management of Severe Brain Injury suggest the use of EtCO₂ monitoring during prehospital resuscitation and transport whenever possible. In the absence of signs of intracranial hypertension, ventilation should be adjusted to accomplish a PaCO₂ of 35 mm Hg when arterial gas values become available.

Resuscitation in the Presence of Clinical Signs of Herniation

Signs of intracranial hypertension consist of evidence of transtentorial herniation (pupillary dilation or loss of reactivity or motor posturing or flaccidity) or progressive neurologic deterioration not attributable to other causes (e.g., sedation). When such signs occur, aggressive treatment of suspected intracranial hypertension is indicated. Hyperventilation to a PaCO₂ target of approximately 30 mm Hg

should be accomplished by increasing the minute ventilation to approximately 120 to 140 mL/kg per minute or as directed by quantitative CO₂ monitoring. Because hypotension can produce both neurologic deterioration and intracranial hypertension, the use of mannitol is less desirable unless adequate volume resuscitation has been accomplished. If such is the case, however, mannitol should be administered by bolus infusion to establish the optimal osmotic gradient. Under such circumstances, it is critical that the diagnosis and treatment of the neurologic injury be accomplished with utmost haste.

Aggressive restoration of intravascular volume, maintenance of adequate CPP, and avoidance of hypoxia are essential for the management of intracranial hypertension. Volume resuscitation should be vigorous and thorough, with a target of euvolemia. Restrict free water by using isotonic fluids, which makes NS preferable to lactated Ringer solution. Optimally, continuous monitoring of central venous and arterial pressures should be instituted early.

Algorithm 21-3. Evaluation and treatment of the patient with severe traumatic brain injury on arrival at the trauma center. The order of steps is determined by the risk–benefit ratio for individual treatment maneuvers. This algorithm should be viewed as “expert opinion” and used as a framework, which may be useful in guiding an approach to initial hospital management of such patients prior to the initiation of ICP monitoring. (© R.M. Chesnut, MD, reproduced with permission.)

Neuromonitoring

Intracranial Pressure Monitoring

All patients with survivable, severe brain injuries and a significant percentage of those with moderate injuries require continuous ICP monitoring. The most recent revision of the Guidelines for the Management of Severe Brain Injury indicates that class II evidence supports monitoring of all patients with a postresuscitation GCS score equal to or less than 8 who have any CT evidence of intracranial pathology.³⁶ Class III level evidence supports monitoring in patients with severe TBI and a normal CT scan if they have two or three of the following: (a) age older than 40 years, (b) any history of hypotension, or (c) abnormal motor posturing. ICP monitoring in other patients is left to the discretion of the physician. ICP monitoring should be considered in any patient with a GCS score of 12 or less who cannot be closely monitored clinically or whose CT scan demonstrates evidence of intracranial hypertension (i.e., mass lesion, obscured or absent basal cisterns, or midline shift).

Although many techniques are available, the most common involve small fiberoptic or strain gauge catheter tip pressure sensors placed several millimeters into the brain or fluid-coupled catheters placed into the lateral ventricles. The minimally invasive catheters are reliable and have a very low complication rate,³⁷ making them an ideal choice in instances where a minimum-risk ICP monitoring technique is desired (e.g., in a moderate head injury that needs general anesthetic). They are also useful when the ventricles are too small to cannulate or there is an uncorrected coagulopathy. Ventriculostomy catheters have the added capability of allowing CSF drainage for ICP control. They are technically more difficult to place, and the complication rate is somewhat higher at 1% to 7%.³⁸ Rarely, however, do catheter-associated hemorrhages require surgical drainage.

Monitoring ICP not only provides early warning of herniation but also, by allowing calculation of CPP, opens up the possibility of more precisely optimizing CBF and preventing ischemic secondary brain injury. Because all methods of lowering ICP or raising CPP have potentially harmful side effects, using such agents to treat suspected intracranial hypertension without monitoring ICP is not recommended. In hospital settings where ICP monitoring is not possible, recent evidence suggests that hourly neurologic examination by a physician may serve as a proxy for ICP monitoring. In most of the developed world, such routine reevaluation by a physician would be extremely resource intensive, and invasive ICP monitoring remains the preferred method when it is available.^{39,40}

Monitoring of Cerebral Perfusion and Oxygenation

Preventing cerebral ischemia is a mainstay in the management of severe TBI patients. There are currently several methods that are readily available for ICU measurement of the adequacy of cerebral oxygen delivery.

Placing a catheter into the jugular bulb via a retrograde venous route allows sampling of the saturation of oxygen in the blood leaving the brain. Jugular venous oxygen saturation values below 50% are associated with cerebral ischemia and worsened recovery, whereas saturations above approximately 85% suggest hyperemic flow.⁴¹ It should be noted that this method averages a large volume of the brain and does not include blood from all of the supratentorial parenchyma so that it cannot completely rule out ischemia.

An alternative monitoring method is the insertion of an oxygen-sensing (Clark) electrode into the brain parenchyma to measure PBtO₂. PBtO₂ values of less than 20 mm Hg are associated with reduced CBF and poor oxygenation.^{42,43} There is a growing body of evidence supporting the utility of this method, and PBtO₂-directed therapy has been associated with improved outcomes.^{44,45} This technique samples only a very small, focal volume of tissue, so is typically placed into normal brain with the intent of preserving healthy tissue.

Cerebral microdialysis constitutes a third method of monitoring for evidence of cerebral metabolism by allowing the measurement of tissue lactate and pyruvate and calculating the lactate/pyruvate ratio. Like PBtO₂ monitoring, this newer technique also samples a very focal region. At present, although cerebral microdialysis is very sensitive and is being used with growing frequency,⁴⁶ it is primarily considered as a research tool.

Monitors that directly measure CBF are also available for clinical use. These monitors measure flow through a thermal dilution method, and can also provide real-time brain temperature and tissue thermal conductivity, which is a measure of parenchymal water content. In conjunction with CPP data, a CBF monitor can help determine the status of a patient's autoregulatory function.⁴⁷ Additionally, noninvasive optical techniques for measuring CBF are showing promising preliminary results, although they have yet to be adopted into mainstream clinical practice.^{48–51}

Of note, these monitors are not mutually exclusive. They may be used to supplement each other or to verify findings from one technique that are suspect. Such a consideration becomes particularly important when significant prolongation or escalation of therapy is being considered based on an abnormal value from one monitoring system. In many practices, cerebral oxygenation monitors are placed in any patient who receives an ICP monitor.

Medical Intervention

Neurocritical Care after Stabilization

Once stabilized, most patients with a positive CT scan merit observation in a neurologic intensive care unit for hourly observation for at least 24 hours. For patients with severe TBI, the length of ICU stay is typically several days. In these patients, the importance of meticulous general critical care is important, because the protracted ICU stay and the necessity for intubation, mechanical ventilation, and other

artificial support systems significantly increase the risk of nosocomial and iatrogenic complications.

Venous drainage of the brain should be facilitated by avoiding constriction of the jugular system in the neck and elevating the head of the bed in euvoletic patients. In addition, attention should be paid to intrathoracic pressures, particularly when considering the use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). Increased intra-abdominal pressure can also decrease venous return, compromise jugular drainage, and elevate ICP.

Fever will elevate ICP and is independently correlated with decreased recovery in severe TBI. Local measures (e.g., cooling blankets, fans) should be used in conjunction with acetaminophen to keep temperatures below 37.5°C to 38°C when ICP requires treatment.

In patients presenting with radiographic evidence of intracranial injury or GCS less than 8, administration of prophylactic antiepileptic drugs is indicated for 7 days postinjury to prevent early seizures.⁵² Patients with early seizures should continue antiepileptics and follow up with an epilepsy specialist for subsequent management.

4 Recent investigations in the trauma population have demonstrated an increased risk of complications in patients who undergo blood transfusion, such as the acute respiratory distress syndrome and the systemic inflammatory response syndrome. A recent randomized controlled trial demonstrated more complications when patients were transfused to maintain a hemoglobin of 10 g/dL versus 7 g/dL.⁵³ Based on this trial, hemoglobin should be maintained at or above 7 g/dL.

Control of Established Intracranial Hypertension

All of the previously discussed “pre-ICP monitoring” steps may be used in direct response to intracranial hypertension, their application and intensity tapered to achieve ICP control. These interventions should be considered the basic steps in this respect and should be optimized prior to adding further treatments.

CSF drainage, hyperventilation, mannitol, barbiturates, and so on are the mainstays of therapy to control intracranial hypertension. Each, however, has significant potential complications, which can obviate their beneficial effects. Therefore, they should not be employed unless intracranial hypertension is established by monitoring ICP, and caution and vigilance must attend their usage. Although the treatment of intracranial hypertension is not the primary focus of this chapter, some brief comments will be useful.

As noted, the treatment of intracranial hypertension should be initiated on a base of adequate sedation and analgesia, control of fever, and optimization of systemic physiologic conditions that might exacerbate ICP elevation (e.g., intrathoracic pressure). Neuromuscular blockade may be added to sedation and analgesia if further ICP control is desired. It does not always work, so a trial should be initiated to determine whether the patient is a “responder” before considering long-term use. Blockade to the level of one to two twitches out of a train-of-four is a reasonable target in this population.

Treatment for intracranial hypertension in adults from the original edition of the Guidelines for the Management of Severe Brain Injury is outlined in [Algorithm 21-4](#). When consulting this algorithm, remember that it represents a consensus opinion (class III evidence) and that, for this reason, a treatment algorithm was not included in the 2008 revision. When this algorithm was developed, the role of hypertonic saline was not addressed. More recently, a consensus-based best practices for TBI was developed by the American College of Surgeon’s Trauma Quality Improvement Program.²⁴ These best practices are an extension of the Severe Brain Injury Guidelines and are meant to provide expert opinion where class I and II evidences are lacking. A depiction of how these guidelines might be applied in clinical practice is depicted in [Figure 21-7](#).

When available via ventriculostomy, CSF drainage should be the first method of managing intracranial hypertension. There is no consensus on what pattern of drainage is most efficacious. It must be noted that ICP measurement cannot be performed when the ventricular catheter is open to drain. For this reason, we generally drain intermittently for several minutes, then reclamp the catheter and measure the ICP. Requiring such cycling more than five times in 1 hour constitutes a need for consideration of therapeutic escalation.

Cerebral Edema and Osmolar Therapy

Cerebral edema during the early postinjury period is generally cytotoxic (intracellular). Later, vasogenic (extracellular) edema may also play a role in brain swelling. Although resulting from different mechanisms (cellular membrane dysfunction and blood–brain barrier breakdown), our present treatment for cerebral edema in trauma is limited to the administration of osmotic agents, most classically mannitol. Generalizing the documented efficacy of corticosteroids to decrease tumor-related cerebral edema to the setting of trauma-induced edema has proven to be ineffective and actually

harmful and is now considered contraindicated.⁵⁴

Algorithm 21-4. Treatment of established intracranial hypertension, based on the Guidelines for the Management of Severe Brain Injury. The order of steps is determined by the risk-benefit ratio for individual treatment maneuvers. This algorithm should be viewed as “expert opinion” and used as a framework, which may be useful in guiding an approach to elevated ICP.

Figure 21-7. A tiered approach to management of intracranial hypertension: increasing levels of intervention are associated with increased complications.

Hyperosmolar agents increase the osmotic gradient, drawing fluid from the interstitial compartment into plasma, thereby reducing brain volume. In regions where the blood–brain barrier has been disrupted, however, such agents are minimally effective and can actually leak into tissues.⁵⁵ The extravasated hyperosmolar agent then functions as an osmotic sink, drawing in free water and paradoxically increasing parenchymal edema. Fortunately, the area of blood–brain barrier breakdown is generally much smaller than the area of edema that it creates so that hyperosmolar therapy is generally effective in lowering ICP. Caution should be exercised, however, as mannitol can produce significant

diuresis. The resulting hypovolemia can result in hypotension which, as described above, can be deleterious to patient outcomes.

More recently, the use of hypertonic saline to elevate serum osmolarity has become increasingly incorporated into pediatric TBI management. In this population, it can help control intracranial hypertension, although its use has not yet been confirmed with rigorous clinical study. In those studies, 3% sodium chloride solution has generally been used, infused at 0.5 to 1.0 mL/kg per hour. As a result of such publications, the Guidelines for the Management of Severe Pediatric Brain Injury contained recommendations placing the use of hypertonic saline-based osmotherapy at the same level as the use of mannitol, leaving the choice to the physician.⁵⁶

In the treatment of adult TBI, no evidence exists for the routine usage of hypertonic saline infusion to induce iatrogenic hyponatremia. In bolus form, 23.4% saline is effective in acutely lowering ICP, while at the same time increasing the intravascular volume. Because it does not cause diuresis, it may be preferred over mannitol when hypotension is present. Rigorous, randomized comparison data on its relative efficacy and duration with respect to mannitol are lacking.^{57,58} There is some data to suggest there is a dose-dependent effect on the duration of ICP control.⁵⁹ Regardless of which agent is chosen, hyperosmolar agents are most effective at controlling ICP when given as a bolus. It should be noted, however, that rapid infusion of higher concentrations of hypertonic saline through a central line can produce temporary asystole.

If hyperosmolar agents have been administered multiple times, when withdrawing therapy, the serum sodium and osmolarity should be allowed to return to within normal limits prior to removing the ICP monitor. The risk of rebound intracranial hypertension associated with the administration of hypotonic solutions such as half-NS or lactated Ringer solution can thereby be minimized.

Barbiturate Coma and Paralysis

In patients who have failed to respond to the above methods, barbiturate coma and paralysis can be effective methods for controlling intracranial hypertension.^{60–62} These interventions do have the drawback of reducing the neurologic examination to just pupillary response. In such cases, neuromonitoring data such as ICP, PBrO₂, and JVO₂ must be used to evaluate whether the patient has responded adequately to the intervention, or if surgical intervention is required. Barbiturate coma can also cause hypotension, so care should be taken to maintain adequate MAP and CPP in during its use.⁶³

Surgical Intervention

When ICP control does not respond to medical management steps, surgical management must be considered. Indeed, with each escalation in medical therapy, surgical intervention should be considered: large mass lesions, for example, or widespread cerebral contusions will often require eventual surgical decompression, so it is preferable to operate before all medical options are exhausted.

Skull Fracture (Including Basal Skull Fractures)

Skull fractures are a common result of head trauma and, when closed and not displaced, rarely require treatment per se. Depressed skull fractures are easily seen on plain frontal or lateral skull films and on CT. The mechanism of injury is usually a direct blow to the skull by a blunt object. Closed depressed skull fractures that are comminuted and those with a fragmented outer margin displaced beneath the inner table have characteristically been treated surgically, although growing evidence indicates that many may be treated nonoperatively if there is no neurologic dysfunction or CT evidence of underlying tissue injury. The best available evidence does not support elevation for the prevention or treatment of epilepsy.

Open fractures are also generally treated surgically, although, again, growing evidence indicates that fresh, noncomminuted fractures without neurologic deficit, CSF or brain extrusion, gross contamination, or underlying tissue injury can be closed and treated with prophylactic antibiotics. When surgery is indicated, the primary goal is to avoid infection by containing CSF, and closing the wound in a manner to ensure healing. Cosmesis is a secondary consideration. Once a fracture has been determined to be operative, early operation is recommended to reduce the incidence of infection. All management strategies for open (compound), depressed fractures should include antibiotics regardless of whether surgery is undertaken. The exact nature of the antibiotics used and the duration of treatment remain inadequately delineated in the existing literature. The general tendency is the use of broad-spectrum antibiotics (vs. gram-positive and gram-negative aerobic and anaerobic bacteria) for 5 days if soft tissue coverage is achieved.^{64–67} In cases where soft tissue coverage is impossible, the duration of antibiotic usage is not

well studied, but should probably continue for at least 2 weeks. Indications for nonoperative management are given in [Table 21-2](#).

Table 21-2 Indications for Nonoperative Management of Compound Depressed Skull Fractures

No clinical or radiographic evidence of:
■ Gross wound contamination
■ Significant intracranial hematoma
■ Gross cosmetic deformity
■ Frontal sinus involvement
■ Dural penetration
■ Depression >1 cm
■ Wound infection
■ Pneumocephalus

5 Basilar skull fractures are usually diagnosed with CT imaging or on clinical evidence, as they are poorly visualized on plain films. Clinical signs include otorrhea or rhinorrhea, subcutaneous ecchymoses overlying the mastoid region (Battle sign), bilateral periorbital ecchymoses (raccoon eyes), or hemotympanum. A basilar skull fracture may involve the paranasal sinuses, piriform sinus, petrous bone, sphenoid sinus, or sella turcica. Injuries to adjacent structures, such as the seventh or eighth cranial nerves, brainstem, and carotid or basilar arteries, are not uncommon. These are generally visualized with CT scanning, although special protocols may be required. If vascular injury is suggested (such as by fracture lines involving the carotid canal), CT or catheter angiography should be considered. In the acute CSF leak, no specific therapy is indicated. The leak should not be tamponaded unless it is brisk. Antibiotics should not be administered solely for prophylaxis of meningitis. Most CSF leaks stop spontaneously with minimal treatment (e.g., elevating the head of the bed). Leaks that continue more than 72 hours generally require temporary CSF diversion (e.g., via lumbar drainage or ventriculostomy). CSF drainage that does not respond to diversion will require surgery.⁶⁸ Although most instances of rhinorrhea cease without surgery, the most common operation for persistent CSF leaks is exploration of the floor of the frontal fossa. The goal of such surgery is to identify the dural defect (often associated with herniation of a small tongue of brain tissue) and either close it primarily, patch it, or otherwise isolate the subarachnoid compartment from the skull base.

Epidural Hematomas

Epidural hematomas are frequently of arterial origin and have a tendency to expand. Prognosis varies directly with level of consciousness at time of surgery, ranging from 0% mortality for patients conscious throughout, to 27% with the classic lucid interval, to over 50% if the patient never regains consciousness. Aggressive surgical management has resulted in an overall mortality of about 9%.³³

The recommendations regarding the management of epidural hematomas contained in the Guidelines for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: an epidural hematoma larger than 30 mL, clot thickness greater than 15 mm, or midline shift over 5 mm should be surgically evacuated regardless of the patient’s GCS score. In patients with a GCS score of 8 or less, evacuation should be emergent. If the GCS score is higher than 8, evacuation should be done as soon as possible but must not interfere with other resuscitative efforts unless there is evidence of progressive deterioration. It is strongly recommended that patients with any acute epidural hematoma with anisocoria undergo surgical evacuation as soon as possible. Epidural hematomas of less than 30 mL, clot thickness below 15 mm, and midline shift less than 5 mm should be considered for evacuation because the risk of evacuation appears less than the dangers of enlargement and neurologic injury. Epidural hematomas of this size in patients with GCS scores above 8 may be considered for nonoperative management, including frequent neurologic monitoring in an ICU setting and serial CT imaging. Although the mean time for enlargement of such lesions is approximately 8 hours after trauma, they may occur at intervals up to 36 hours.

Subdural Hematomas

Subdural hematomas are the more common extra-axial mass lesion, particularly in non–motor vehicle trauma. For acute subdural hematomas, the prognosis is less optimistic, with mortality rates of approximately 50%. To a great extent, this is related to the often significant injury to the underlying brain.

The recommendations regarding the management of subdural hematomas contained in the Guidelines

for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: an acute subdural hematoma with a thickness greater than 10 mm or midline shift above 5 mm on CT should be surgically evacuated, regardless of the patient's GCS score. Evacuation should be on an emergency basis if the initial GCS score is less than 8. In patients with higher GCS scores, evacuation should be as soon as reasonably possible. A comatose patient (GCS score 8) with a subdural hematoma with less than 10 mm thickness and midline shift below 5 mm should undergo surgical evacuation of the lesion if any of the following apply:

- The GCS score decreased between the time of injury and hospital admission by 2 or more GCS points.
- The patient presents with asymmetric or fixed and dilated pupil(s).
- The ICP exceeds 20 mm Hg for more than 5 to 10 minutes.

Patients with subdural hematomas of less than 10 mm thickness and midline shift below 5 mm and GCS scores greater than 8 can be treated nonoperatively, but should be closely observed.

It appears that outcome from subdural hematomas is proportional to the timing of evacuation. When surgery is planned, it should be performed within 4 hours whenever possible.⁶⁹ If surgical evacuation of an acute subdural hematoma in a comatose patient (GCS score 8) is indicated, it should be done using a full craniotomy with or without bone flap removal and duraplasty.

Frequently, consideration is given to leaving off the bone flap following the evacuation of acute subdural hematomas, particularly when the surgeon feels that there is evidence of brain swelling (e.g., brain herniation above craniotomy), or a perceived risk of subsequent brain swelling (e.g., significant preoperative midline shift). Unfortunately, there is a relative dearth of information on this group of patients.

Parenchymal Lesions

Surgery for intraparenchymal mass lesions remains controversial. Arguments against surgery include the risks of the operation itself as well as damage to tissue that may otherwise go on to recover. Arguments for surgery focus on preventing the hazards of intracranial hypertension caused by the lesion itself or progressive edema formation as the lesion matures. Much of the difficulty in determining the applicability of surgery in individual situations arises from our inability to consistently predict which patients will rapidly deteriorate (e.g., proceed on to herniation) or fail nonoperative therapy by developing intracranial hypertension refractory to medical therapy.

Recommendations regarding the management of traumatic parenchymal lesions contained in the Guidelines for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: in general, patients with any lesion greater than 50 mL in volume should be treated operatively. Additionally, patients who have parenchymal mass lesions and signs of progressive neurologic deterioration referable to the lesion, medically refractory intracranial hypertension, or signs of mass effect on CT scan should be considered for surgery.

Patients with GCS scores of 6 to 8 should be treated operatively if they have frontal or temporal contusions greater than 20 mL in volume with either midline shift over 5 mm or cisternal compression on CT scan.

Patients with parenchymal mass lesions may be managed nonoperatively if they do not show evidence for neurologic compromise, have controlled ICP, and have no significant signs of mass effect on CT scan. Such patients should be managed with intensive monitoring, frequent clinical examination, and serial imaging. Surgery should be readdressed if difficulties with control of intracranial hypertension lead to consideration of "higher-tier" therapies (e.g., hypothermia or barbiturate coma) so as to avoid the secondary complications of such therapy. In all nonoperatively treated patients with parenchymal mass lesions, surgery should be considered before reaching the medical "point of failure."

Surgical management may involve decompression to "make room" for the lesion-induced swelling, evacuation and débridement of the offending lesions, or a combination. Because evacuation of such lesions does not always eliminate the development of intracranial hypertension, extensive craniotomy with expansible duraplasty and without replacing the bone flap should be considered at the time of operation.

Diffuse Injury

The mortality rate of diffuse brain injury is directly related to the significance of the associated intracranial hypertension. As such, the mortality rate of diffuse injury with open basilar cisterns is approximately 13%, whereas compression or absence of cisterns has an associated mortality rate of about 38%. Diffuse injuries are not amenable to surgical therapy unless decompressive craniectomy is

indicated for control of intractable intracranial hypertension. Although a recent study suggested that decompressive bifrontal craniectomy led to unfavorable outcomes in these patients, flaws in its design (most notably, significant dissimilarity in the severity of neurologic injury between the treatment and the control groups) called into question the validity of its conclusions.^{70–72}

DAI is a reasonably distinct subset of diffuse brain injury. It is characterized on CT scan as small areas of focal hemorrhage in the brainstem, thalamus or deep nuclear region, corpus callosum, and hemispheric white matter, which may be associated with cerebral swelling. Intracranial hypertension is an inconsistent part of this syndrome. When ICP is elevated, however, successful management improves outcome. These patients tend to recover to varying extents; many of them will significantly improve in their level of consciousness but will generally be left with diffuse neurologic deficits (e.g., spasticity, cognitive impairments). Although a favorable prognosis seems to be correlated with fewer lesions on imaging studies and early improvement in level of consciousness, prognostication is difficult in individual cases of DAI.

Posterior Fossa Lesions

Posterior fossa lesions are particularly dangerous because the progression from a benign lesion to a critical lesion is so precipitous and deadly. Patients may rapidly deteriorate from awake and alert to comatose, with signs of herniation (“upward” [caused by uncompensated swelling in the posterior fossa] or “downward” [from hydrocephalus]). Because of difficulties with the technology and uncertainty as to what pressures might be critical, monitoring of posterior fossa ICP is rarely performed. Vigilant clinical observation, tempered with a high degree of preemptive concern, therefore, represents the only form of monitoring currently applicable.

The recommendations regarding the management of traumatic posterior fossa lesions contained in the Guidelines for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: rapid suboccipital craniectomy for evacuation of acute traumatic posterior fossa mass lesions is recommended in patients with neurologic dysfunction or deterioration referable to the lesion or mass effect on CT scan. Mass effect on CT scan appears as distortion, dislocation, or obliteration of the fourth ventricle; compression or loss of visualization of the basal cisterns; or presence of obstructive hydrocephalus.

In general, surgery is recommended for any clot larger than 3 cm in diameter, whereas conservative management may be considered with clots smaller than 3 cm when not associated with acute subdural or epidural hematomas. Because of the potential for rapid, unheralded deterioration, evacuation should be performed as soon as possible in patients with indications for surgical intervention.

Penetrating Injuries

Penetrating injuries to the brain present several unique management problems, including the prophylaxis and treatment of intracranial infection, the possibility of epilepsy, and the risk of occult vascular injuries. The recommendations regarding the management of penetrating brain trauma contained in the Guidelines for the Management of PBI²³ can be summarized as follows: Although plain radiographs may be useful in determining intracranial trajectory, CT scanning of the head is the modality of choice in PBI. In addition to the standard axial views with bone and soft tissue windows, coronal sections may be helpful in patients with skull base or high convexity involvement.

Angiography or CT angiography should be considered in patients with PBI. It is strongly recommended in cases in which the wound’s trajectory passes through or near the Sylvian fissure, supraclinoid carotid, cavernous sinus, or a major venous sinus because of the increased risk of traumatic aneurysm or arteriovenous malformation. Sentinel signs of vascular abnormalities are large initial hematomas or the delayed development of substantial and otherwise unexplained subarachnoid hemorrhage or hematoma. When discovered, such vascular lesions should be definitively managed.

A major complication of penetrating injury is infection, both meningitis and abscess. Most infections occur within 3 weeks (55%) to 6 weeks (90%). The major risk factors appear to be CSF leaks, air sinus wounds, or wound dehiscence. The incidence of infection with the use of broad-spectrum antibiotic treatment ranges from 1% to 11%. Although the main causative agent appears to be *Staphylococcus*, gram-negative bacteria are also frequent and *Clostridium* or other anaerobic organisms may be found with appropriate culture techniques. As such, antibiotic prophylaxis is indicated in all penetrating injuries. Broad-spectrum regimens, including anaerobic coverage, lasting for 7 to 14 days appear to be a reasonable approach.

Seizures are much more frequent following PBI than nonpenetrating injury in general. Between 30% and 50% of patients with PBI develop seizures. Although class I data are lacking, the increased incidence

of early seizures has led to the recommendation that antiseizure medications (e.g., phenytoin, carbamazepine, valproate, phenobarbital) should be used during the first week after PBI. Prophylactic treatment with anticonvulsants beyond the first week after PBI has not been shown to prevent the development of new seizures and is not recommended.

The surgical management of penetrating wounds to the brain has undergone significant evolution over the past two decades. At present, surgical débridement of the missile tract in the brain is not recommended in the absence of significant mass effect. As well, routine surgical removal of fragments lodged distant from the entry site or reoperation solely to remove retained bone or missile fragments is not recommended.

Treatment of small bullet entrance wounds to the head in patients whose scalp is not devitalized and have no significant intracranial pathology should consist of local wound care and closure. In more extensive wounds with nonviable scalp, bone, or dura, surgical management with more extensive débridement followed by primary closure or grafting to secure a watertight wound is recommended. Closure of the dura and prevention of CSF leakage are extremely important goals in managing penetrating wounds. In patients with significant fragmentation of the skull, débridement of the cranial wound with either craniectomy or craniotomy is recommended.

Figure 21-8. Location for placement of initial exploratory burr hole in the temporal region for emergency diagnosis and decompression.

Mass lesions should be surgically managed to prevent intracranial hypertension. As such, débridement of necrotic brain tissue and safely accessible bone fragments is recommended when they produce significant mass effect. As well, evacuation of intracranial hematomas is recommended if they produce significant mass effect as defined by the production of midline shift of over 5 mm or intracranial hypertension. This is one of the reasons that monitoring of ICP in penetrating injuries is an important adjunct to surgical decision making.

Repair of an open air sinus injury with watertight closure of the dura is recommended.

Exploratory Burr Holes/Craniotomy

If there is a high clinical suspicion for a mass lesion and CT imaging is unavailable, exploratory burr holes can be a useful and lifesaving option. If signs of herniation are present, all attempts should be made to reverse it medically (with hyperventilation and hyperosmolar agents as described above) so that the patient may be transferred to a facility equipped with CT capabilities.

If no such facility is reachable, or if herniation is refractory to medical management, emergency burr holes is a useful and lifesaving option. The first burr hole is placed in the ipsilateral temporal region and the dura is opened if an epidural hematoma is not in evidence (Fig. 21-8). If this exploration is negative, a second hole is placed in the opposite temporal region, then at the region of the parietal boss and the frontal convexity, first on the ipsilateral side, then contralaterally. A burr hole exploration is considered negative when six holes have been drilled. Any positive burr hole is turned into a craniotomy, and the hematoma is thoroughly evacuated.

Decompressive Craniectomy for Control of Intracranial Hypertension

In the eventuality that lower-tier interventions have been unsuccessful at controlling intracranial hypertension, decompressive hemicraniectomy should be considered. By effectively expanding the

intracranial volume, decompressive hemicraniectomy allows the swollen brain additional room to expand and can improve ICP.

These craniectomies involve intentionally removing large, fronto-temporo-parietal bone flaps, leaving them out, and widely opening the dura to prevent it from constraining the bulging brain. The most common scenario is that of diffuse swelling wherein the more affected side is chosen for decompression. In cases where edema is bilaterally symmetric, bilateral decompressive craniectomies can be performed. In a recent randomized controlled trial, bilateral frontal hemicraniectomy was not found to improve outcomes,⁷⁰ but this result is controversial because of technical flaws in the study.⁷² Regardless of which method is chosen, the bone flaps are as large as possible and particular attention is paid to decompressing the temporal lobe by removing the temporal bone forming the lateral wall of the middle cranial fossa.

Complications related to surgical management of TBI, especially after craniectomies, occur in a predictable temporal progression.⁷³ In the hours and days following surgery, pre-existing hemorrhagic lesions may undergo expansion partly because this is their natural history, and partly because of decreased tamponade on the lesion itself.⁷⁴ Wound infection and CSF leaks are most commonly seen in the initial week following surgery, and the incidence of complication ranges from 4% to 35%.^{75,76} Posttraumatic hydrocephalus is a delayed complication presenting weeks to months following injury. Ventriculomegaly, secondary to encephalomalacia of injured brain tissue or alterations of CSF dynamics after TBI, is found in up to 45% of patients with hemicraniectomy following severe TBI.^{77,78}

Given the high rates of morbidity from hemicraniectomy, this procedure should be applied cautiously, and only after an honest appraisal of the patient's recovery potential. Patients who have suffered prolonged periods of hypotension or hypoxemia, patients without evidence of brainstem function, and patients with advanced age or multiple medical comorbidities have increased postsurgical and overall risk and are less likely to benefit from surgery.⁷⁹ Additionally, patients on anticoagulation or antiplatelet agents that are irreversible are unlikely to benefit from hemicraniectomy. Finally, patients with catastrophic injury on computerized tomography scan, as quantified by the prognostically oriented Rotterdam score, make poor surgical candidates.⁸⁰ Judiciously applied, surgical decompression can be a lifesaving operation that has an acceptable risk profile given a severe TBI.

Chapter 22

Maxillofacial Injuries

Batya R. Goldwaser, Leonard B. Kaban, and Maria J. Troulis

Key Points

- 1 Due to the widespread use of seatbelts and airbags, the overall incidence of MVC-related injuries has decreased, but improved survival has resulted in increased complexity of injuries requiring treatment.
 - 2 Life-threatening maxillofacial injuries involve upper airway obstruction and/or hemorrhage.
 - 3 Identification of injuries to specialized structures including the facial nerve, parotid duct, the globe and lacrimal system is critical.
 - 4 Fractures of the maxilla and mandible are unique because of the presence of teeth which are the most important landmark for reduction. The primary goal of treatment is restoration of the dental occlusion.
 - 5 Maxillary fractures involve the pterygoid plates and are classified as Le Fort I, II or, III depending on the superior extent of the injury.
 - 6 Indications for operative treatment of zygomaticomaxillary complex (ZMC) fractures include cosmetic deformity, enophthalmos or diplopia, paresthesia, and limitation of mouth opening from coronoid impingement.
 - 7 The status of the medial canthal ligament and its attachment to bone is the key to proper diagnosis and treatment of naso-orbital–ethmoid (NOE) fractures.
 - 8 Retrobulbar hematoma and extraocular muscle entrapment are surgical emergencies that require immediate treatment to prevent permanent visual deficits.
 - 9 Indications for operative treatment of frontal sinus fractures include cosmetic deformity, intracranial extension, and nasofrontal outflow tract obstruction. Complications include meningitis and mucocele formation which can occur even years later.
 - 10 Indications for open treatment of mandible fractures include edentulism, severe displacement, or comorbid conditions that preclude closed reduction with maxillomandibular fixation, or the presence of concomitant midface fractures.
 - 11 All mandible fractures of the tooth-bearing region are considered open fractures and antibiotic treatment must be instituted.
 - 12 In panfacial fractures, various treatment approaches including “top-down,” “bottom-up,” and “outside-in” exist, and are chosen based on the specific injury pattern.
-

1 The etiology of facial trauma in adults is most commonly motor vehicle crashes, followed by interpersonal violence, sports injuries, and falls, with the exact incidence varying by geographic location. Among children, falls predominate followed by sports injuries and motor vehicle collisions.¹ Although firearm-related deaths have declined, head and neck injuries continue to make up approximately 15% of gunshot wounds, often a result of suicide or homicide.² Young males (age 20 to 30) make up the largest group demographically for all causes of facial trauma, while children account for less than 10%.³ In adults, the most commonly injured structures are the nose, dentoalveolar complex, zygoma, and mandible given their protrusive position relative to the rest of the face. Orbit and midface (i.e., Le Fort level) injuries are less common. The opposite is true in children whose cranium grows rapidly and results in a prominent forehead and orbits and a larger skull-to-face ratio with the midface relatively protected. Mandibular, nasal and dentoalveolar trauma is most common.⁴ Due to the widespread use of seatbelts and airbags, the incidence of MVC-related injuries has decreased. However, severely injured patients have improved survival resulting in an increase in the complexity of midface and mandibular fractures and overlying soft tissue injuries now seen.^{5,6}

TREATMENT OF LIFE-THREATENING CONDITIONS

2 The initial management of a patient with facial trauma, like all trauma patients, begins with the standard ATLS protocol including breathing, airway, and circulation.⁷ Specific life-threatening maxillofacial injuries involve upper airway obstruction and/or hemorrhage and must be addressed acutely.^{8,9} Aspiration of blood or foreign bodies (including teeth, dentures, debris, and stomach contents), the tongue position especially in unconscious patients or those with certain unstable mandible fractures (i.e., “bucket-handle”), or midface fractures with resultant impaction of the maxilla can obstruct the airway. The high correlation between facial trauma and C-spine injuries requires clinical and radiographic exclusion of concomitant fractures and/or ligamentous injury.

Facial injuries causing significant bleeding are not common, with the exception of scalp and tongue lacerations which must be addressed quickly. The ethmoidal arteries as well as branches of the internal maxillary artery can also be a source of significant bleeding (Fig. 22-1). Hemostasis is usually attained with head elevation, pressure and packing with gauze, an inflated Foley catheter, or Rhinorockets. If bleeding continues despite these measures, diagnostic imaging such as CTA, and fracture reduction and immobilization, with or without direct ligation or embolization may be required (Fig. 22-2).⁹⁻¹²

3 The secondary survey involves examination of soft tissue and bony injuries, including specialized structures such as the facial nerve, the parotid duct, the globe, and the lacrimal system. Stepoffs and/or mobility of the orbital rims, malar eminences, zygomatic arch, nasal bones, and mandible signify displaced fractures. Mobility of the maxilla should be determined and all teeth should be accounted for, either by direct visualization or ruling out aspiration by chest x-ray. Nerve paralysis, any sensory deficits, or malocclusion almost always correlate with a significant facial injury.

Figure 22-1. Sources of bleeding in facial trauma.

SOFT TISSUE INJURIES

Important anatomic regions of the face that must be precisely reapproximated include the vermillion border of the lip, the eyebrow, and the eyelid where even small inaccuracies in repair can become larger deformities later. Defects of up to 25% of the lip or eyelid can be closed primarily with good results. Eyelid lacerations involving the medial third must be closely evaluated to identify the punctum and canaliculus which drains into the nasolacrimal duct to the inferior meatus in the nose. Retrobulbar hematoma is a surgical emergency that must be immediately decompressed to prevent permanent vision loss. Signs include decreasing visual acuity, elevated intraocular pressure (IOP) (>40), pain, tense globe, proptosis, and often a visible hematoma on imaging. Treatment is with immediate lateral canthotomy and cantholysis for decompression (Figs. 22-3 and 22-4).¹³

The nasal septum and ear pinna must be checked for hematoma which can lead to cartilage necrosis (with subsequent “saddle nose deformity” or “cauliflower ear”) if not evacuated. Following drainage, a bolster should be placed to prevent reaccumulation. Any injury along the course of the facial nerve proximal to the lateral canthus should be suspect for injury to a major branch and repaired primarily (Fig. 22-5).

Injuries to the parotid gland and duct must be identified. To identify ductal injury or continuity

defects, the Stenson duct orifice (best found at the papilla adjacent to the maxillary second molar) is visualized while simultaneously “milking” the parotid gland from extraorally in the direction of salivary flow. If the duct is intact, saliva should be visible flowing from the orifice into the mouth. However, lack of salivary flow does not confirm ductal injury, as flow can be minimal in multiple conditions such as dehydration or autoimmune disorders. Comparison to the contralateral or uninjured side can help in differentiating acute injury. Another maneuver that can be diagnostic is cannulating the duct using a lacrimal probe and following the path as far proximally as possible. If the duct has been transected, the probe may be visible within the facial wound. Midductal injuries require proximal and distal segment reanastomosis, usually over a catheter which is left in place for 10 to 14 days. Distal ductal injuries can be left open to the mouth with creation of a neoorifice.^{14,15} For intraglandular injury, the parotid capsule may be closed and a pressure dressing placed to prevent development of a sialocele (Fig. 22-6).

Figure 22-2. The patient was acutely stabilized by the trauma service (Drs DeMoya and Velmahos). **A,B:** Bleeding was acutely controlled by packing for the ascending pharyngeal artery, cauterization of the ethmoidal arteries, and immobilization of the midface. **C:** The laceration was temporarily closed.

Figure 22-3. **A,B:** At the initial operation, the right globe was found to be ruptured and thus exenterated. The left globe had increased intraocular pressure, was tense and had limited extraocular movements on forced duction so an emergent lateral canthotomy was performed with immediate decompression. The nasolacrimal apparatus was cannulated by the oculoplastics service and noted to be severed.

4 Fractures of the maxilla and mandible differ from other fractures because of the presence of teeth which are the most important landmark for reduction and render fractures as “open.” The goal of treatment is not only reduction, fixation, and immobilization, improved contour, and range of motion, but also restoration of occlusion. Although in the acute or emergent setting the airway should be secured by any means necessary, when planning definitive treatment, the requirement for access to the occlusion will determine whether oral, nasal, or submental intubation is most appropriate. An oral tube can be used if the patient is edentulous or has many missing teeth without a reproducible occlusion. Nasal intubation is generally safe even with significant midface trauma, but is best performed under

direct visualization with fiberoptic guidance to prevent inadvertent intracranial injury. When nasal intubation is not possible and the occlusion must be established, submental intubation is a useful alternative. Oral intubation is followed by passing the oral end of the endotracheal tube through an incision in the floor of mouth and submental neck. Postoperatively, the tube is passed back into the mouth and the patient can be extubated. If prolonged assisted ventilation is anticipated, an elective tracheostomy should be considered preoperatively.

Figure 22-4. Lateral canthotomy. **A:** Canthal tendon anatomy. **B:** Lateral canthotomy. After clamping the tissue for hemostasis, a horizontal cut is made with scissors through skin, orbicularis oculi, and conjunctiva of the lateral palpebral fissure. This is usually not sufficient to reduce intraocular pressure (IOP). **C:** Inferior cantholysis. Next, the lower lid is retracted to expose the inferior limb of the canthal tendon which is oriented horizontally. After dissecting it free, the tendon is cut with scissors oriented vertically. Though not usually required, if IOP is still elevated, the superior limb can be dissected free and transected as well.

Related to choice of airway, fractures of the tooth-bearing maxilla and/or mandible require the patient to be on a nonchew diet for 6 weeks. After a 1-week inflammatory phase, a soft callus forms over 2 to 3 weeks. At this point the fracture is stable enough to prevent shortening but it is still susceptible to angular forces. A hard callus then replaces the soft callus and can take up to 3 to 4 months. For this reason, it is generally recommended to limit chewing forces for 6 weeks (in adults) and to avoid additional trauma for 3 months.¹⁶ If there are minimal concomitant injuries, most patients are able to maintain nutritional requirements with enteral intake, often with oral supplements. If there are other significant injuries, especially those resulting in altered mental status or prolonged ICU stay, a nasogastric tube or gastrostomy tube may be needed.

MAXILLARY FRACTURES

5 The famous study by Rene Le fort in 1901 is the basis for the current classification system of maxillary fractures (Fig. 22-7).¹⁷ Physical examination reveals periorbital ecchymosis and edema, epistaxis, a retruded midface, palatal ecchymosis, malocclusion, numbness in the V2 distribution, mobility of the maxilla at the piriforms, nasofrontal or zygomaticotemporal sutures. Epiphora results if the nasolacrimal duct is obstructed.

Computed tomography (CT) is the imaging modality of choice for midface injuries, especially if the orbit is involved or if an operation is planned. Treatment includes reduction, and usually disimpaction of the maxilla, using the occlusion as a guide when possible, followed by immobilization (either maxillomandibular fixation or rigid fixation to an adjacent stable facial structure) (Fig. 22-8).

Figure 22-5. A,B: The left facial nerve was explored given the location of the laceration (i.e., proximal to the lateral canthus) and a severed branch to the upper lip was anastomosed under microscopic visualization by Dr. Hadlock.

ZYGOMATICOMAXILLARY COMPLEX FRACTURES

The zygoma articulates with the frontal, sphenoid, temporal and maxillary bones, forming a “complex” (Fig. 22-9). It also forms the infraorbital rim and orbital floor. Physical examination shows periorbital ecchymosis and edema, flattening of the cheek, downslanting of the lateral canthus, enophthalmos, or stepoff at the infraorbital rim. Paresthesia of the infraorbital distribution suggests nerve entrapment in the line of fracture. Less common is limitation of mouth opening which occurs if the zygomatic arch is depressed and impinges on the coronoid process of the mandible. Because of the close association with the orbit, a preoperative ophthalmology examination is prudent.¹⁸

CT scan is the gold standard in order to best appreciate the degree of rotation and/or depression, as well as to evaluate the orbital floor component. Historically, the Water view radiograph was used, and it is with this image that the well-known and still used Knight and North Classification system was developed.¹⁹ This classification system which describes zygomaticomaxillary complex (ZMC) fractures by rotation, depression, and comminution, predicts fracture stability after reduction. With the use of CT scans and rigid fixation, this classification system may not be as relevant. Another classification system developed by Manson in 1990 divides ZMC fractures into low-energy, mid-energy, and high-energy fractures.²⁰

Figure 22-6. A,B: The left parotid duct was cannulated and clear salivary flow identified. A stent was left in place for 21 days.

Figure 22-7. A: Le Fort I fractures are horizontal fractures that span across the piriform rims along the floor of the nose, through the maxillary sinus around to the pterygoid plates posteriorly. Le Fort II fractures are pyramidal in shape and include the nasal bones, infraorbital rims, in addition to the zygomaticomaxillary buttress and pterygoid plates. Le Fort III is a separation of the entire face from the skull base and includes the nasofrontal suture and medial orbit, zygomaticotemporal suture at the lateral orbit around to the pterygoid plates. B,C: Maxillofacial CT of the same patient as above, showing Le Fort I, II, III level fractures and significantly displaced bilateral mandibular body fractures. A CTA and subsequent angiogram showed transection of the bilateral internal maxillary arteries without a target for embolization.

6 Surgical treatment is usually delayed until swelling resolves to better evaluate any cosmetic deformity and to allow easier surgical access if needed. Nondisplaced, stable fractures can be observed. Indications for open treatment include cosmetic deformity, enophthalmos, or diplopia when the orbital floor component is significant, paresthesia of the V2 distribution and limitation of mouth opening from coronoid impingement. If there is enophthalmos, or high likelihood of future enophthalmos secondary to herniation of orbital contents into the maxillary sinus, dystopia, or diplopia that does not resolve once the swelling goes down, the orbital floor will also require reconstruction (see also orbital fractures) (Figs. 22-8 and 22-10).²¹⁻²⁴

NASO-ORBITAL–ETHMOID FRACTURES

Naso-orbital–ethmoid (NOE), a term coined in 1973, describes a facial subunit that is widely considered to be the most complex of all facial fractures that is uncommonly injured, comprising only 2% to 15% of all facial fractures, and rarely occurs in isolation (usually accompanied by midface or frontal sinus fractures).²⁵ The complex consists of the medial orbital walls, nasal bones, frontal process of the maxilla, nasal process of the frontal bone, and the ethmoid sinuses. Bleeding may be secondary to injury of the anterior or posterior ethmoidal arteries along the medial orbital wall. The clinical examination is most notable for periorbital ecchymosis and edema, subconjunctival hemorrhage, a depressed nasal radix with a wide or flattened dorsum and upturned tip, and telecanthus with increased intercanthal distance to over 35 mm. CSF rhinorrhea may be present if the cribriform plate is involved, as can enophthalmos, depending on the degree of medial orbital volume increase. Epiphora may also be present if there is damage to the lacrimal drainage system. A complete ophthalmologic examination is required to rule out ocular injury.¹⁸

Figure 22-8. Same patient after open reduction and internal fixation of the bilateral Le Fort I, II, and III fractures, after repairing the mandible and using the occlusion as a guide to work from bottom-up. **A:** Intraoperative photos of Le Fort I ORIF. **B:** Postop CT scan.

Figure 22-9. **A:** Lateral view of CT scan from same patient showing partial facial amputation. **B:** ZMC fracture and mandibular subcondylar and angle fractures highlighted. **C,D:** Postop CT scan showing reduction and fixation of ZMC and mandible fracture.

Figure 22-10. The zygomaticofrontal suture was reduced and plated. After releasing the infraorbital nerve from the fractured orbital floor, the zygomas were rigidly fixated at the piriform rims, the zygomaticomaxillary buttresses and infraorbital rims.

7 The status of the medial canthus and its attachment to bone is the key to proper diagnosis and treatment. In 1991, Markowitz and Manson published one of the most well-known studies on NOE fractures (Fig. 22-11).²⁶ CT scan is the gold standard for diagnosing and classifying NOE fractures. Though it is difficult to visualize the tendon itself, the fracture can be classified based on the degree of comminution.

Definitive treatment can be delayed for swelling or stabilization of other injuries, but ideally not beyond 2 weeks as reduction becomes difficult. The goals of treatment include restoring the intercanthal distance, orbital volume, dorsal support, and nasal tip projection and length. Incompletely reduced telecanthus is one of the most difficult complications to treat so overcorrection should always be attempted.²⁷⁻³²

Figure 22-11. A: They classified fractures into type I (medial canthal tendon attached to a single large segment of bone), type II (comminuted bony segment but canthus remains attached to sizeable fragment) and type III (severe comminution and/or avulsion of the canthal tendon). **B:** Intraoperative view of same patient showing reduction and fixation of nasofrontal suture and left infraorbital rim. The medial canthal tendon was also identified and resuspended under the nasal bones to the contralateral medial orbit.

ORBITAL FRACTURES

Related to, and often part of both ZMC and NOE fractures are orbital fractures. The superior, lateral, and inferior orbital rims are very dense, while the medial orbital rim and wall, as well as the orbital floor are very thin, often less than 0.5 mm; therefore, trauma to the orbit usually results in fracture of the thin floor or medial wall, termed “blow-out” fractures if isolated (Fig. 22-12).

8 Extraocular muscle entrapment is a surgical emergency, evaluated by testing extraocular movements in the awake patient, or forced duction testing in a noncooperative or comatose patient, in all ZMC, NOE, and isolated orbital fractures. Entrapment is most common in young patients who have elastic bone and periosteum with a small “trapdoor” seen on CT scan of the floor or medial orbit (Fig. 22-13).

The other indication for open treatment is enophthalmos. This can be treated in a delayed fashion and can often be predicted based on CT findings even before the swelling has resolved if the defect is large (>50%), there is significant herniation of orbital contents into the sinus or if the orbital rim is displaced. Immediate (within 2 weeks) versus delayed repair often depends on surgeon preference (Fig. 22-8).³³⁻³⁵

FRONTAL SINUS INJURIES

9 Frontal sinus fractures often occur in conjunction with NOE or other midface fractures. Anterior table fractures may result in significant cosmetic deformity if displaced. The nasofrontal outflow tract drains the frontal sinus to the ethmoid sinuses. If this passage is found to be obstructed, it must be sealed off with temporalis fascia, pericranium, cranial bone, or tissue sealants, followed by obliteration of the sinus mucosa and filling the dead space to prevent infection and delayed mucocele formation.

Posterior table fractures can cause intracranial injury and should be evaluated in conjunction with neurosurgery. If the displacement is significant or there is evidence of dural tear or frontal lobe injury, the posterior table should be removed along with the sinus mucosa and the nasofrontal outflow tract obstructed. Then the sinus is cranialized and the anterior table can be reconstructed.³⁶⁻³⁸

MANDIBLE FRACTURES

The diagnosis of a mandible fracture can usually be made by history and physical examination alone. In addition, a panoramic radiograph (actually a sagittal view) is underappreciated in terms of its ability to show the presence and type of fracture. The panoramic x-ray, together with another plain film at 90 degrees (i.e. PA skull film), identifies the degree and direction of displacement, and can obviate the need for a CT scan. In reality however, a CT is often obtained in the emergency room for screening of other injuries.

On examination, findings often include numbness of the inferior alveolar nerve distribution (if the fracture is between the mandibular and mental foramina), malocclusion, gross mobility, jaw deviation, and gingival lacerations or sublingual ecchymosis. Bleeding from the external auditory meatus should raise suspicion for a mandibular condyle or temporal bone fracture. Because the mandible is U-shaped, force from one blow is distributed around the arch and often results in a second fracture. Common patterns include a blow to the symphysis resulting in bilateral condylar fractures, or a blow to the parasymphysis resulting in a contracoup injury to the opposite condyle. The presence of teeth also impact fracture pattern, the most common of which is the third molar, especially if impacted, which increases the risk of a mandibular angle fracture. Teeth in the line of fracture may be left in place as they can aid in reduction; if they impede reduction, extraction is required.^{39,40}

Figure 22-12. A,B: The left orbital floor was explored and reconstructed with titanium mesh. A silastic implant holder was placed into the right orbit to provide contour for a future prosthetic implant by the oculoplastics team.

Figure 22-13. A different patient who sustained a left orbital floor blow-out fracture with entrapment of the inferior rectus muscle. A: Clinical photo demonstrating limitation of upward gaze. B: Sagittal reformat of CT showing entrapment of left inferior rectus. C: Coronal reformat showing the same.

Some mandible fractures can be treated with closed reduction and maxillomandibular fixation in dentate patients. Severely comminuted fractures, such as in a gunshot wound, may also be treated closed, to avoid stripping the periosteum and therefore blood supply from small fragments (Fig. 22-14). Immobilization is maintained for 4 to 6 weeks in adults, 6 to 8 weeks in the elderly, and 2 to 4 weeks in children (Fig. 22-15).

10 Indications for open treatment include fractures in edentulous patients as there are no teeth to guide reduction and the bone is often atrophic, requiring load-bearing rigid fixation. Other indications include severe displacement that is not easily reduced, or comorbid conditions that preclude wiring the patient closed (i.e., seizure disorder, alcoholism, and psychiatric issues). In the presence of concomitant midface fractures, a mandible fracture may be treated open in order to establish a stable landmark and building block to work from (Figs. 22-8, 22-9, and Fig. 22-15).⁴¹⁻⁴⁶

Figure 22-14. Patient with comminuted mandible fracture treated with closed reduction and maxillomandibular fixation to avoid stripping small bone fragments of periosteal blood supply.

Figure 22-15. **A:** Reduction and immobilization was performed using maxillomandibular fixation. **B:** The left mandibular angle fracture was rigidly fixated. The right subcondylar fracture (see above) was treated with closed reduction and immobilization.

Treatment of mandibular condyle fractures remains with some controversy in maxillofacial trauma. In general, high subcondylar or intracapsular fractures are generally treated closed as there is little bone to plate and bleeding into the joint increases the risk of ankylosis.^{47–52} These fractures are treated with early mobilization to maintain range of motion. Low subcondylar fractures are generally treated similar to other extra-articular mandibular fractures. In the past few decades, minimally invasive endoscopic approaches to treatment of mandibular condyle fractures have been used for open treatment with good results.^{53–55}

11 Because any fracture within the tooth-bearing segments is considered an open fracture, and is at higher risk of infection, antibiotics and immobilization should be initiated as soon as possible. Postop antibiotics, while common practice, have not been shown to decrease the infection risk.⁵⁶ Long-term complications following mandible fractures include malocclusion, infected hardware, or osteomyelitis. Delayed initial treatment or inadequate immobilization increases the risk.

Figure 22-16. The patient recovered well. His residual deficits were left facial nerve weakness as well as loss of the right eye.

APPROACH TO PANFACIAL FRACTURES

12 Various approaches including “top-down,” “bottom-up,” and “outside-in” exist and are chosen based on the specific injury pattern. In general, the uninjured cranial base is used as the building block for repair of the upper face while the maxillomandibular complex is used to rebuild the lower face. Then these two subunits are unified at the Le Fort I level. For the cranio-orbital subunit, reduction can commence at lateral orbital rims and move inward, or at the NOE and move outward. The dentition is the most useful landmark for rebuilding the maxillomandibular subunit in conjunction with establishing the posterior vertical facial height by reducing the mandibular ramus/condyle unit (Fig. 22-16).^{20,57-61} Lack of sufficient projection is the usual problem (Fig. 22-17).

In summary, maxillofacial trauma presents a wide range of diagnostic and treatment challenges. Following acute treatment of life-threatening airway and bleeding concerns, definitive treatment involves careful repair of hard and soft tissue structures, ideally within 2 weeks. With improved survival, presenting injuries are more complex and successful reconstruction requires an appreciation of facial subunits and their interconnection.

Figure 22-17. A: Patient treated after 5-story fall. Inadequate projection and resultant facial widening. B: Reoperation with osteotomies and bone repositioning lead in better projection and normalized width.

Chapter 23

Neck Injuries

Brandon R. Bruns and Thomas M. Scalea

Key Points

- 1 An intimate understanding of the neck anatomy is imperative for optimal management.
 - 2 Obtaining a secure airway is vital for management of all injuries, especially those in the neck.
 - 3 Gentle digital pressure or balloon tamponade presents opportunities to control life-threatening hemorrhage from vascular injuries in the neck.
 - 4 Though classic teaching mandated exploration of zone II injuries, modern practice has strayed from this concept.
 - 5 Blunt cerebrovascular injury must be considered, diagnosed, and treated in patients at risk for the disease.
 - 6 Blunt cerebrovascular injury is often present in patients who do not manifest traditional screening criteria.
 - 7 A combination of endoscopy and contrast-enhanced radiography presents the best opportunity to diagnose esophageal injury when present.
-

1 Many vital structures reside within the neck and exist in close proximity to one another. These include aerodigestive, vascular, bony, and neurologic organs. These intimate relationships can lead to multiple injuries of varying complexity in a wide variety of structures within a relatively small area. Of penetrating injuries to the neck, the vast majority are caused by stab wounds.¹⁻³ Blunt injury to the neck is the result of various mechanisms of injury including direct blows, automobile shoulder belts, and various hanging mechanisms with neck hyperextension. The anatomic complexity and diverse injury mechanisms make diagnosing and treating neck injuries challenging.

FUNCTIONAL ANATOMY

The exterior anatomic barriers of the neck include the lower border of the mandible anteriorly to the nuchal line of the occipital bone posteriorly. Inferiorly, the clavicles serve as the anterior border with a line drawn toward the seventh cervical vertebral spinous process encompassing the posterior border.

Triangles are classically used to divide the neck into zones, however they are only rarely used to classify and plan treatment in the trauma patients. The posterior triangles are bordered by the sternocleidomastoid muscles anteriorly, the trapezius muscles posteriorly, and the clavicles inferiorly. The anterior triangles are bordered by the sternocleidomastoid muscles, the midline, and the angles of the mandible bilaterally.

In 1969, Monson and colleagues⁴ arbitrarily divided the neck into three anatomic zones: zone I consisted of the area below the sternal notch, zone II was the area between the clavicles and the mandibles, and zone III was described as the upper cervical region and consisted of the area above the mandibles. Roon and Christensen⁵ introduced a more modern version of the neck zones in 1979 and defined zone II as the area between the cricoid and the angle of the mandible, zone I as the area below the cricoid cartilage, and zone III remained the area above the mandibular angle ([Fig. 23-1](#)).

The zones of the neck are important as the approach to injury within each zone is different. This is particularly true when one considers vascular exposure. All major vascular structures in zone II can be readily accessed via a standard sternocleidomastoid neck incision. Via a single incision, proximal and distal vascular control can both be obtained within zone II and injuries repaired.

However, proximal control for zone I injuries requires control within the chest. A variety of incisions can be used depending on the location of the injury. A full sternotomy provides access to the mediastinal great vessels and the proximal left subclavian artery, along with the origin of the left

common carotid artery. If a smaller incision is indicated, a partial sternotomy allows control of the innominate artery. A periclavicular incision provides access to the bilateral subclavian arteries. In short, a variety of incisions may be needed for full exposure. After proximal control, subsequent distal control can then be obtained in zone II.

Proximal control for zone III injuries can be obtained in zone II without much difficulty. However, distal control may be very difficult as the mandible and skull base prevent wide exposure. Several methods such as mandibular subluxation or osteotomy have been described to control the carotid artery at the base of the skull.⁶ A muscle splitting incision can also help give access to the carotid artery and the base of the skull.⁷

Figure 23-1. Zones of the neck.

The inferior and lateral extensions of zone I are often contested and debated. While this is not well described, our practice is to classify lateral and inferior (superior mediastinal) injuries by zone I principles. Because proximal control involves a thoracic incision, we believe zone I extends to the junction of the subclavian and axillary arteries laterally and inferiorly to the mediastinal great vessels.

Injury to the posterior neck should be treated differently than injury to the anterior neck. It makes sense that tracheal and esophageal injuries would be less common with posterior injury, as they are protected by the spine. Injuries to the spine should be more common in this anatomic region.

Often, more than one zone can be injured by a single trajectory; such as an injury through both zone II and zone I. Management of these “multizone” injuries is guided by the standard principles used for the more challenging zone, usually zone I or zone III.

The platysma muscle envelops the neck and originates from the pectoralis major and deltoid muscles. Though clinical practice has evolved, most classic algorithms of treating penetrating neck trauma stated that injuries penetrating the platysma muscle in zone II of the neck mandated direct operative intervention, whereas those penetrating the platysma in zones I and III mandated additional studies via either angiography or other imaging modalities.⁵

INITIAL MANAGEMENT

2 Basic trauma management of patients with injury to the neck should proceed as outlined in the American College of Surgeons course Advanced Trauma Life Support (ATLS).⁸ Initial priority is given to securing the patient’s airway. Every patient with a neck injury should be considered for early airway control. A wise clinician should plan airway control in all patients with evidence of neck injury and select the few in whom airway control is not needed. Even in seemingly stable and hemostatic patients, rebleeding can produce sudden and disastrous symptoms and sequelae. An airway that had previously been straightforward to control is now much more complicated and may require advanced techniques.

Obvious injury to the neck, with the presence of an expanding hematoma or other hard signs of vascular injury, should lead the provider to obtain definitive endotracheal access as the first step in the resuscitation. Similarly, air bubbling through the wound, hoarseness, or an obviously transected trachea, should guide the treatment team toward immediate and definitive airway control.

In the event that orotracheal intubation cannot proceed (rapidly expanding hematoma, destructive laryngeal trauma, patient habitus, excessive debris within the oropharynx, etc.); an emergent surgical airway should be expeditiously obtained. Cricothyroidotomy and emergency tracheostomy remain the

safest and most reliable methods of emergent surgical control of the airway. Some investigators have shown promising results with percutaneous tracheostomy performed in the emergency setting, though this should only be contemplated by experienced clinicians.⁹ If tracheal transection is visualized in the wound, intubation of the distal tracheal segment with an endotracheal tube or any available airway device can be lifesaving (Fig. 23-2).

Though obtaining a safe and definitive airway is the priority in all injured patients with airway compromise, awareness of potential concomitant cervical spine injury must be considered in patients with blunt trauma. Maintaining cervical stabilization during movement and intubation is paramount and is best accomplished by maintaining the head and neck in neutral position with the help of a competent assistant trained in such maneuvers. The same caution is not needed in patients with penetrating trauma, as patients presenting alive and neurologically intact are highly unlikely to have unstable cervical spine fractures.^{10,11}

Figure 23-2. Intubation of a distal tracheal transection in the neck.

3 After securing an adequate airway, patient care should proceed in an orderly fashion by using ATLS principles with the next priorities being breathing and circulation. In evaluating the chest, the clinician must remain aware that penetrating injury to zone I can violate the cupula of the lung and result in pneumothorax or hemothorax, which may require evacuation. Circulatory issues focus on intravenous access with resuscitation and assessment of the blood pressure, but it also entails control of any obviously bleeding focus. Pulsatile bleeding emanating from a neck wound is best managed with gentle digital compression. Occasionally, a urinary catheter or a Fogarty catheter can be delicately placed into a bleeding neck wound with gradual inflation of the balloon in an attempt to tamponade hemorrhage. The catheter should be inserted as far as it goes easily and the balloon is then inflated and the catheter gently pulled back until bleeding eases.

A rapid assessment of the neurologic state of the patient can give insight into the nature of a neck injury, as a dense hemiplegia may be the result of carotid arterial injury and subsequent ischemic stroke. It is imperative to recognize the patient with a lateralizing neurologic defect early, as revascularization may result in hemorrhagic conversion of a cerebral infarction.

After the primary survey and adjunctive radiographic procedures (chest radiograph, abdominal sonography), a thorough secondary survey should be performed, with focus on the structures of the neck. A hematoma across the base of the neck, which was caused by an automobile seatbelt, may portend a blunt cerebrovascular injury (BCVI). Extensive subcutaneous emphysema in the tissues of the neck usually represents air tracking up from a pneumothorax, but can represent an injury to the airway. Injury to the esophagus is possible, but subcutaneous air is rarely the only symptom of esophageal injury. Similarly, an audible bruit or palpable thrill may indicate major vascular injury that requires prompt attention.

SELECTIVE VERSUS MANDATORY EXPLORATION

Few would argue that penetrating injuries to the neck, with hard signs of injury (pulsatile hemorrhage, expanding hematoma, shock, air emanating from the wound, massive hemoptysis), mandate immediate surgical exploration. In the absence of these hard signs of injury, most favor a selective approach with

clinical examination and diagnostic radiographs.

Overall Approach

4 Early surgical teaching mandated exploration for penetrating zone II neck injuries that violate the platysma muscle, regardless of the presence or absence of hard signs of injury. Those who support the concept of mandatory exploration have cited the low incidence of significant morbidity with surgical exploration, despite the high likelihood of negative exploration.^{2,12} Proponents also point to the lack of physical examination findings in patients that did proceed to surgical exploration that had injuries present at operation.³ In contradistinction to mandatory exploration, many investigators advocate a more selective approach to operative therapy, suggesting surgery only in symptomatic patients. Authors supportive of the more limited approach cite a low morbidity and mortality associated with observation of zone II injuries and high likelihood of negative exploration.¹

While diagnostic exploration may make sense for zone II injuries, diagnostic preoperative evaluation certainly makes sense for injuries in zone I and zone III. Penetrating injury in zone I puts vascular structures, trachea, and esophagus at risk. Physical examination can be misleading and different incisions may be needed depending on which structures are injured and the level at which they are injured. Thus, in stable patients, diagnostic work up is wise. This generally involves endoscopy, contrast studies, or both to investigate the possibility of an esophageal injury. While asymptomatic tracheal injuries are quite rare, many have favored a diagnostic bronchoscopy in these injuries. In the past, vascular structures were investigated by means of catheter angiography, with noninvasive axial imaging as the most common modality in the current era.

Unfortunately, in unstable patients with a zone I trajectory, localization of the injury may not be possible preoperatively. In such a case, the clinician should make an estimate as to which structures are most likely to be injured. The initial incision should be tailored to quickly expose that area. If exposure is inadequate or a different structure has been injured, the incision should be lengthened, or a second incision should be made. This process continues until the injury is controlled or the patient has died.

Aerodigestive injuries are not an issue in zone III; however the difficulty in surgical management of vascular injuries in zone III makes preoperative imaging very attractive. In the past, angiography was used as the sole diagnostic test in stable patients. If patients are unstable, clinicians must weigh the difficulty of diagnostic exploration against the time it would take to use alternative hemostatic methods. In some cases, if catheter hemostasis is immediately available, temporary control with finger pressure or a balloon, as a bridge to rapid diagnostic angiography and catheter hemostasis may actually be quicker than direct operative exploration. In most areas of the world, this approach is only appropriate in a few highly advanced centers. In most centers, while difficult, direct surgical exploration is the wisest course in the unstable patient.

Current Imaging Technology

In recent years, computed tomography (CT) has become much more widely used to evaluate the possibility of neck injury. CT is extremely attractive as it is a single study that is rapidly available in virtually every center and provides a three-dimensional evaluation of the neck. In patients with injury patterns that put the upper mediastinal structures at risk as well, CT can evaluate both areas for potential injury, simultaneously. CT may be very effective at excluding injuries in some cases. For example, a patient with a gunshot wound to the neck that has a clearly demonstrated CT trajectory that avoids all vital structures, most likely only needs observation and no additional diagnostic testing. Other patients, such as those with significant amounts of subcutaneous air or a trajectory that is close to vital structures, such as the carotid artery and/or the esophagus, may need additional diagnostic testing.

Penetrating Neck Trauma

In 2002, Gonzalez et al. prospectively evaluated patients with penetrating injury to zone II of the neck that did not have an indication for emergent surgical exploration.¹³ Patients then underwent dynamic CT imaging and had a barium esophagram, followed by mandatory surgical exploration of the neck. Investigators noted a total of four esophageal injuries, two of which were seen on surgical exploration only and were not identified on either CT scan or esophagram. However, both injuries missed on diagnostic evaluation were less than 0.5 cm and were the result of stab wounds. The authors speculated that the injuries may have healed spontaneously. The most commonly missed injury by CT scan was jugular venous injury; which likely needed no therapy.¹³

In a large prospective study involving Los Angeles County, University of Southern California Medical

Center, and the R Adams Cowley Shock Trauma Center at the University of Maryland, all asymptomatic patients presenting with a penetrating neck injury and no signs of injury were safely observed and investigators reported zero missed injuries. In the same series, patients with soft signs of injury (venous oozing, nonexpanding or nonpulsatile hematomas, minor hemoptysis, dysphonia, dysphagia, and subcutaneous emphysema) underwent multidetector CT angiography (CTA). Investigators achieved 100% sensitivity and 97.5% specificity in detecting all clinically significant injuries.¹⁴

Blunt Neck Trauma

Plain film radiography is not adequate to identify injuries to structures in the neck. However pneumothorax, hemothorax, air in the subcutaneous tissues, nasogastric tube displacement, or mediastinal widening are all indicative of significant force that would be sufficient to injure structures within the neck.

BCVI diagnosis deserves special mention, as disagreement still persists as to the optimal screening test for diagnosis. In the past, BCVI was usually diagnosed late, after the patient had suffered a stroke. Diagnostic angiography then virtually always demonstrated an internal carotid artery injury. Therapy included anticoagulation, but was mainly supportive as the damage had already been done. Additionally, catheter angiography is invasive and carries some risk of iatrogenic vascular injury and/or periprocedural stroke.

5 As screening protocols were developed, the incidence of BCVI seemed to increase, even in patients with no identifiable risk factors for BCVI.¹⁵ As CTA became more entrenched as a diagnostic tool, the rate of vascular injury again seemingly radically increased.^{16,17} It seems obvious that the patients did not change, but our ability to diagnose injuries did. This is very similar to recent experience with pulmonary embolism, where our ability to diagnose these conditions is greatly increased with the use of CTA. This obviated the need for multiple diagnostic studies such as ventilation perfusion scans and/or pulmonary angiography. One must question whether some of these injuries, particularly those of low grade, have significant clinical importance.

Additional debate has focused on the ideal test for diagnosis of BCVI, with some suggesting angiography and some CTA. In a study of 146 patients at risk for BCVI, investigators imaged all patients with 16-slice CTA and four-vessel cerebral angiography. They noted a sensitivity of 97.7% and a specificity of 100% with the utilization of CTA for the diagnosis of BCVI.¹⁸ However, authors in Memphis examined 684 patients and found the sensitivity of CTA to be 51% with a specificity of 97%.¹⁹ Despite the disparate findings, survey results illustrate that 90% of trauma surgeons utilize CTA as their preferred diagnostic modality for BCVI.²⁰

MANAGEMENT OF SPECIFIC INJURIES

Blunt Cerebrovascular Injury (BCVI)

Blunt injuries to the carotid and vertebral arteries are the result of a direct blow to the vessel itself or an extreme flexion, extension, or lateral rotational injury. If located in the carotid artery, these injuries typically occur at the base of the skull. Vertebral artery injury usually is located in the portion of the vessel protected by the cervical spine. These areas are difficult to explore surgically.

6 BCVI is reported to occur in 1% to 2% of blunt trauma patients and the incidence of stroke is approximately 25%, with a mortality rate of up to 13%, if left untreated.^{16,21,22-24} Treatment for these injuries is centered on antiplatelet therapy and systemic anticoagulation to decrease the risk of stroke. Early recognition and initiation of treatment has been shown to decrease the rate of cerebral ischemia.^{25,26}

The work of Biffl and colleagues in 1999^{21,24} highlighted the importance of screening for BCVI when certain anatomic injuries or injury patterns were observed (Table 23-1). Subsequently, organizational guidelines have been disseminated by the Eastern Association for the Surgery of Trauma (EAST) based on review of the literature with the aim of guiding screening practices for BCVI (Table 23-2).²⁷ Investigators have shown that up to 30% of patients diagnosed with BCVI may have no radiographic or clinical risk factor that would guide the clinician to screen for these injuries.¹⁵ Recent data has also identified an association between BCVI and nontraditional risk factors such as serious chest injury.¹⁷ Thus, a high index of suspicion must be maintained in order to effectively diagnose and treat BCVI.

Given the seeming inability of screening guidelines to accurately identify patients at risk for BCVI,

some centers have gone to blanket screening.¹⁵ All polytrauma patients with a blunt mechanism of injury undergo CT scan of the cervical spine with contrast timed to image the carotid and vertebral arteries in conjunction with a chest and abdominal CT scan, obviating the need for a second contrast study. While data on this blanket screening is limited, it does enable the identification of injuries early in the course of workup and identifies injuries in patients that would otherwise not be screened secondary to lack of criteria.¹⁵ Patients with identified injuries generally receive a formal CT angiogram as their follow-up study.

If stroke can be avoided with prompt initiation of therapy, functional outcomes after BCVI are good.²⁸ However, many patients with BCVI have multisystem trauma and are thus not deemed suitable for antiplatelet therapy or systemic anticoagulation. In a 2009 study, almost one-third of patients with BCVI were identified as not candidates for therapy, with an overall stroke rate of 12%. Stroke-related mortality was 50%.¹⁶

Table 23-1 Signs and Symptoms of Blunt Cerebrovascular Injury

Hemorrhage of potential arterial origin
Expanding cervical hematoma
Cervical bruit in a patient <50 years old after trauma
Unexplained lateralizing neurologic deficits, transient ischemic attack, amaurosis fugax, or Horner syndrome after trauma
Cranial neurologic deficits incongruous with brain CT findings
Evidence of cerebral infarction on CT scan

Table 23-2 Screening Criteria for Blunt Cerebrovascular Injury

Injury mechanism
Severe cervical hyperextension/rotation or hyperflexion, particularly if associated with
Displaced midface or complex mandibular fracture
Closed head injury inconsistent with diffuse axonal injury
Near hanging result in anoxic brain injury
Physical signs
Seat belt abrasion or other soft tissue injury of the neck resulting in swelling or altered mental status
Fracture in proximity to internal carotid or vertebral artery
Basilar skull fracture involving the carotid canal
Cervical vertebral body fracture

From Bromberg WJ, Collier BC, Diebel LN, et al. Blunt cerebrovascular injury practice management guidelines: The eastern association for the surgery of trauma. *J Trauma* 2010;68(2):471–477.

It is tempting to assign treatment for BCVI to a relatively lower priority. Patients with BCVI often have concomitant injuries such as intra-abdominal solid visceral injury or traumatic brain injuries. The traditional approach has been to simply decide that these patients are not candidates for anticoagulation and defer therapy. While this may be acceptable with low-grade injuries, given the relatively high rate of stroke with higher-grade injuries, this may not be wise. Recent data suggest that in Grade IV carotid injuries (complete occlusion), recanalization and subsequent stroke is extremely common.²⁹ This would seem to suggest that the presence of higher-grade injuries mandates therapy. For instance, in a patient with splenic injury and carotid artery injury, one should consider whether splenectomy followed by anticoagulation is wiser than nonoperative management and withholding treatment for the BCVI.

OPERATIVE EXPLORATION

After making the decision to proceed to the operating room, the operating surgeon and surgical team should quickly consider the various anatomic injuries which may be present. This is important as many general surgeons do not commonly operate in the neck. Simply considering what may be found and reviewing treatment options may help.

The patient should be positioned in a supine manner with a full surgical prep from the chin to the knees. Utilizing a widely prepped surgical field enables the surgical team to expeditiously access various

body cavities as the operation mandates. If unilaterality of injury is assumed or known, it may be beneficial to position the patient's head in the direction opposite to the injury, which opens the surgical field for better exploration. Given the very real possibility of a "multizone" injury, a sternal saw should be immediately available for possible entry into the mediastinum. Similarly, a chest retractor and deep vascular instruments should be immediately available.

Penetrating Vascular Injury

The presentation of penetrating vascular injury in the neck is dependent on the vessel injured and its location. Arterial injuries, specifically the carotid arteries, present with pulsatile arterial hemorrhage emanating from the wound or a rapidly expanding hematoma. Venous injuries tend to have a more insidious presentation and may be clinically undetectable. Penetrating vertebral artery injury is rarer given the relatively protected position of the artery within the osseous spinal canal.

Cerebral ischemia secondary to carotid artery injury can lead to stroke and long-term neurologic sequelae, or even death. In some series, patients who present in hemorrhagic shock have a mortality of 41%, but have 50% mortality when presenting with stroke.³⁰ Patients presenting with any neurologic deficit short of coma should undergo carotid arterial repair with revascularization if technically feasible, as results are improved with revascularization. In patients presenting with a glasgow coma score (GCS) <8 (coma), a poor outcome is likely regardless of the therapy selected.^{31,32}

Often, carotid artery injury is diagnosed intraoperatively, as there is no time for preoperative imaging. These injuries are usually cared for using the standard principles to treat vascular injuries. The neck is explored through a generous sternocleidomastoid incision. The proximal carotid artery is controlled at the base of zone II. If possible, it is wise to control the artery distally, before entering the hematoma. Unfortunately, this is often not possible. As the neck is a compact structure, during dissection to control the distal carotid, the contained hematoma often ruptures. Digital control can then be used to prevent exsanguinating hemorrhage while the distal dissection is carried out. Once the distal carotid artery, whether it is the internal carotid artery or distal common artery, is controlled, distal pressure can be released and more careful dissection continued.

Injuries to the common carotid artery can sometimes be repaired primarily, particularly if the injury is caused by a stab wound. More complex injuries, as those from gunshot wounds, usually require resection. Sometimes, even gunshot wound injuries can be managed with primary repair. Full mobilization of the common carotid artery will often give additional length. For injuries located more distally, ligating the external carotid artery will give additional mobility to the common carotid artery. If primary repair is not feasible, a bypass graft using either saphenous vein or PTFE is equally acceptable. PTFE, of course, should be avoided in the event of contamination or concomitant tracheal or esophageal injury.

Internal carotid artery injury represents a distinct subset of carotid artery injuries. Unlike common carotid artery injury, the initial neurologic presentation is not a good predictor of final neurologic presentation. Injuries to the internal carotid artery have 20% mortality and the majority of these deaths are secondary to cerebral ischemia.²⁶ Interventional techniques including embolism may be effective in some injuries, thus obviating the need for exploration.²⁷

Control of the internal carotid artery proceeds along the same principles as with common carotid artery injuries, though distal control may be problematic. During the dissection, one must take care not to injure the hypoglossal nerve, which passes across the distal internal carotid artery. The surgeon should ascertain adequacy of back bleeding from the distal internal carotid artery. Pulsatile back bleeding confirms patency of the circle of Willis. In patients with poor back bleeding, use of a shunt should be considered. We routinely use full dose IV heparin unless there is a contraindication.

The internal carotid artery can be repaired using the same principles as mentioned for the common carotid artery, though several scenarios require special mention. If there is injury to the proximal internal carotid artery and the distal vessel is thrombosed, dissection should be carried out as distal as possible. If the vessel is thrombosed, as far as surgically accessible, the surgeon should avoid the temptation to do catheter thrombectomy as this is virtually never complete and, once revascularized, the patient has significant risks of embolic stroke. In addition, one should avoid ligating the thrombosed internal carotid artery at the base. If one forcefully ligates the internal carotid artery, there is high likelihood that distal clot will be dislodged, causing a stroke of clinical significance.

Figure 23-3. A proximal internal carotid artery injury managed with resection and transposition of the external carotid artery to obtain inflow to the native internal carotid artery.

Occasionally, one will encounter an injury in the very proximal internal carotid artery. Once the vessels are controlled, consideration should be given to use the external carotid artery as the conduit, if primary repair is not feasible. The damaged internal carotid artery can be dissected down to the level of the bifurcation (Fig. 23-3). The external carotid can be ligated at the level of the first branch and the external carotid artery rotated over to use as the conduit. A single vascular suture line then connects the external to the internal carotid artery.

The external carotid artery, for the most part, is expendable. If an external carotid artery injury is diagnosed at the time of surgical exploration, it can simply be ligated. Those that are diagnosed preoperatively, with images, are often amenable to catheter-based hemostatic techniques.²⁹ If there is a distal injury to a branch of an external carotid artery, such as the facial or lingual arteries, particularly if caused by penetrating facial trauma, catheter-based hemostasis is by far the most attractive option. Proximal ligation of the external carotid artery will decrease inflow, but the robust collateral circulation from the contralateral external carotid may be sufficient to cause continued hemorrhage. Angiographic options are then essentially nil, as the ligated external carotid prevents an angiographic solution.

Secondary to the posterior anatomic location and protection provided by the cervical spine, penetrating vertebral artery injuries are less likely. Additionally, injuries to the vertebral arteries are less likely to cause neurologic sequelae than those to the carotids.³⁰ Operative exposure of the vertebral artery is quite difficult secondary to its protected location in the posterior neck. If necessary, it is best approached via an anterior approach with proximal ligation of vertebral artery.³¹ Combined carotid and vertebral artery penetrating injuries are very morbid, with mortality rates of approximately 50%.³² Occasionally, a vertebral artery injury will be discovered at the time of diagnostic neck exploration. This is an extremely challenging situation, as direct pressure will only temporarily control the artery. Rather than attempting to expose the artery by unroofing the cervical spine over the vessel, we have generally maintained digital pressure or controlled the artery temporarily with a Fogarty balloon, after which the patient can then be transported to a site where angiographic embolization is possible.

Trachea and Larynx

Blunt laryngotracheal trauma is uncommon³³ and low-grade injuries, can be clinically occult. Thus, it requires a high index of suspicion for accurate diagnosis and initiation of treatment. The most typical mechanism of injury involves an anterior to posterior vector of force that drives the thyroid cartilage into the rigid cervical spine. Such forces can be the result of a motor vehicle collision with compression of the neck against the steering wheel or dash of the automobile. The most common symptoms include hoarseness, dyspnea, and dysphagia.^{33,34} Careful attention must be paid to the airway as laryngotracheal separation can be catastrophic. Definitive diagnosis is made with a combination of CT scanning and endoscopy and definitive airway management is best obtained with tracheostomy, if endotracheal intubation is not prudent.³⁵

The presentation of penetrating laryngotracheal injuries are less subtle, as impressive symptoms and physical findings almost always present in high-grade injuries. Management is focused on rapid airway control, either via endotracheal intubation or via a surgical airway. In the rare instance of tracheal transection in the neck with two visible lumens, the distal lumen should be intubated with any available airway device. Concomitant esophageal injury is a source of major morbidity; therefore the esophagus should be evaluated with endoscopy early or operative exploration in the course of treatment.³⁶

Cervical tracheal injuries, particularly if they are isolated, are best approached via a collar incision performed approximately two fingerbreadths above the sternal notch. If other injuries are present

and/or if full exploration is needed, the trachea can be exposed and repaired using a sternocleidomastoid incision. If a collar incision is used, subplatysmal flaps are created and the strap muscles are then divided in the midline. The thyroid isthmus can be retracted cephalad and the entire cervical trachea is then clearly visualized. If the location of the tracheal injury in the neck is clearly in zone II, surgical exploration confirms the diagnosis and allows for prompt therapy.

However, sometimes the injury is located closer to the thoracic inlet. In those cases, preoperative bronchoscopy is vital in order to plan the best operative course. If the injury is located in the upper mediastinum, several options exist. The patient can be explored via a collar incision and the anterior trachea identified. The trachea can be mobilized using digital dissection into the upper mediastinum. The trachea can then be grasped with a tracheal hook and retracted up into the neck. It is possible to mobilize the trachea for approximately three rings, thus allowing the surgeon to repair these injuries with a relatively small incision. However, injuries that are located in the more distal mediastinum are best approached with a right-sided posterolateral thoracotomy.

Occasionally, tracheal injuries will be located at a level above the endotracheal balloon. When performing diagnostic bronchoscopy, the endotracheal tube must be withdrawn over the bronchoscope, up to the level of the vocal cords. This allows complete visualization of the proximal trachea. Not doing this, risks missing the proximal tracheal injury.

Injuries to the posterior membranous trachea are relatively difficult to approach. In patients with blunt trauma, small injuries may be simply observed. However, if repair is thought to be prudent, the best way to approach this is via the anterior trachea. The anterior trachea is opened transversely at the level of the injury and the injury is then visualized and repaired. The anterior trachea is then closed primarily. Intraoperative bronchoscopy can help locate the level of the injury.

The blood supply to the trachea enters posterolaterally on both sides. Therefore, circumferential mobilization of the trachea, risks causing ischemia, which may manifest either as tracheal necrosis, dehiscence of a repair, or postoperative tracheal stenosis. In addition, the recurrent laryngeal nerve runs in the tracheoesophageal groove and care must be taken to avoid damage to it during mobilization or tracheal repair. Postoperatively, patients should be extubated as soon as possible. It is often tempting to think that the tracheal repair is protected with longer-term tracheal intubation, but the chances of complication are less if the patient is extubated at the end of the operative procedure. One should avoid a tracheostomy in a patient with tracheal repair, because stenosis at the level of tracheostomy and the level of tracheal repair can make future reconstruction exceedingly difficult.

Figure 23-4. Partial sternal split for evaluation of tracheal injury. The endotracheal tube balloon is visualized within the lumen of the injured trachea.

In the event that the injury extends into the thoracic inlet, a partial sternal split (Fig. 23-4) or full sternotomy can be performed for better visualization. Tracheal injuries are preferentially repaired primarily with single layer absorbable suture, though resection of up to 2 to 4 cm with primary anastomosis is technically feasible. Suture lines are buttressed with autologous, well-vascularized tissue such as strap muscle (Fig. 23-5).

Esophagus

Figure 23-5. Divided strap muscle utilized to buttress tracheal injury/repair.

Expeditious diagnosis of esophageal injury is imperative, as missed injury and/or a delay in diagnosis can lead to disastrous consequences. In a review of 109 penetrating esophageal injuries, the mortality rate was 2% with immediate operation. Mortality increased to 44% with delayed diagnosis and operation. In this same series, mortality increased to 100% for patients with a delayed diagnosis and no operative procedure.³⁷

As the course of the esophagus is relatively superficial within the neck, diagnosis can occasionally be made on physical examination findings alone. Food particles or salivary secretions within the wound are highly suggestive of esophageal injury. Additional physical examination findings may include esophageal or oropharyngeal bleeding, subcutaneous emphysema, and neck hematoma. Plain film radiographic findings may include air within the subcutaneous tissues and pneumomediastinum.³⁸ In a review of 77 patients with noniatrogenic esophageal injury, 58% occurred in the cervical esophagus but physical examination findings were present in only 26% of the cohort.³⁹

7 Given the pervasive nature of CT scanning in the trauma patient, investigators have evaluated the utility of this imaging modality for esophageal injury. A study from the Aga Khan University Hospital showed 53% sensitivity for CT scanning in diagnosing esophageal injuries.⁴⁰ The gold standard for diagnosis of most esophageal injuries remains a combination of esophagoscopy and contrast-enhanced esophagography. When these two imaging modalities are used in combination, an accuracy of almost 100% is achieved.⁴¹ The sensitivity of esophagography alone varies from 50% to 90% while the sensitivity of endoscopy alone varies from 29% to 100%.⁴²

As with the trachea, the location of the esophageal injury defines the approach for repair. Those injuries that are clearly in zone II can easily be approached via a sternocleidomastoid incision. Those in the chest are best approached via a posterolateral right thoracotomy. As with the trachea, localization of the injury, particularly those at the junction between the neck and chest, is the easiest way to ensure optimal exposure. Intraoperative endoscopy can be very helpful in positively identifying the location of an injury and helping to direct therapy.

Small, nondestructive injuries in the hypopharyngeal region can occasionally be managed nonoperatively with antibiotics, upright positioning, limited oral intake, and close clinical observation.⁴³ However, the vast majority of cervical esophageal injuries are best managed operatively. Cervical esophageal injuries are most easily approached via a left anterior sternocleidomastoid incision. If a collar incision has been initiated, it can be extended to the left, along the anterior border of the sternocleidomastoid muscle to facilitate better exposure. Preoperative placement of a nasogastric tube may assist with identification of the esophagus in the neck, as the hard nasogastric tube can be palpated within the lumen. After lateral retraction of the sternocleidomastoid muscle, the dissection progresses medially until the esophagus is encountered. Care must be taken to avoid injury to the recurrent laryngeal nerve in the tracheoesophageal groove.

Circumferential dissection of the esophagus and placement of large rubber drain around the organ can facilitate retraction and mobilization. As the blood supply of the esophagus runs vertically within the muscle, the esophagus can be circumferentially mobilized without risk of ischemia. Thus, injuries located in the superior mediastinum can be mobilized into the neck and repaired. After repair, liberal drainage of the injured area is highly recommended in an effort to avoid salivary fistula and deep neck infection.^{38,43} Delays in diagnosis of more than 12 hours are associated with poor outcomes and in these

cases, proximal diversion and wide drainage may be the safest option.

Primary repair of the injury is the goal in most circumstances. During repair, the entirety of the mucosal injury must be visualized, as it may extend beyond the field of view under the longitudinal outer muscle of the esophagus. Debridement of all devitalized tissue is required. Repairs are typically performed in two layers with absorbable sutures, though single-layer repair is possible.^{38,44} Similar to tracheal repair, a well-vascularized muscle is highly recommended to buttress the repair. Given the likelihood that the patient will be on a restricted oral diet, placement of a small-bore enteral tube, distal to the repair, should be considered intraoperatively. Imaging repairs at 7 to 10 days with a contrast-enhanced swallow study is recommended prior to removal of drains.

Table 23-3 Common Complications After Neck Injury

Pneumonia and ventilator dependent respiratory failure
Surgical site infection
Anastomotic dehiscence and repair breakdowns
Suture granulomas
Tracheoesophageal fistula

COMPLICATIONS

As in all forms of injury, neck injuries are associated with a variety of morbidities (Table 23-3). The most common complications after tracheal repair include postoperative suture granuloma, pneumonia, and surgical site infection.⁴⁵ Complications after tracheal repair were once thought to be numerous; modern studies have questioned this supposition. In a 2013 paper, investigators showed that complications after tracheal injury alone were associated with an exceedingly low rate of complications. In patients with combined tracheal and esophageal injuries, the rate of complications is drastically increased.⁴⁶

Tracheoesophageal fistula occurs when an abnormal passage forms between the trachea and esophagus, manifesting as respiratory distress and recurrent pulmonary infections. Management includes a variety of operative techniques aimed at restoring the continuity of both the trachea and esophagus and the interposition of well-vascularized tissue flaps between the repairs. Though endoluminal stenting is discussed, its utility is currently minimal.⁴⁷

Esophageal leak from repair dehiscence and anastomotic breakdown creates an ongoing source of intrathoracic infection and inflammation, which makes primary management and repair exceedingly difficult. Though relatively early in the experience, the use of endoluminal stenting in this situation has shown promise and avoids the need for full operative exploration.⁴⁸ Leaks in the neck are more easily controlled by opening of the wound and wide drainage with avoidance of enteral nutrition past the site of injury. In rare instances, cervical esophagostomy may be required.

SUMMARY

Management of injuries to the neck requires a thorough understanding of three-dimensional anatomy and an appreciation for the severity of injuries possible in this region. A relatively small anatomic region, the neck contains many structures vital to meaningful survival. Attention to airway is of the utmost importance, because without a secure airway, the remainder of workup is meaningless. In the presence of vascular injury, all management options must be rapidly reviewed and the most easily obtained and efficacious maneuver should be chosen. As nonoperative management of many traumatic injuries continues to expand, it is the obligation of the surgeon to remember basic surgical principles and apply them in an expeditious and safe manner as the situation mandates.

Chapter 24

Thoracic Trauma

Marc de Moya and George Velmahos

Key Points

- 1 The mortality associated with penetrating thoracic trauma is higher than blunt trauma.
 - 2 The most common thoracic injury is rib fracture and the most effective pain relief is thoracic epidural analgesia.
 - 3 Not all pneumothoraces need to be drained but when necessary drainage can be accomplished effectively with a pigtail catheter.
 - 4 Hemothoraces may be drained by 28-Fr chest tubes and if there is significant retained hemothorax early intervention with video-assisted thoracoscopy should be employed.
 - 5 Aortic injury repair may be delayed and the injury medically managed in the face of significant associated injuries.
-

INTRODUCTION

1 Thoracic trauma is a common occurrence with an incidence of approximately 25% of all traumas.¹ Thoracic injuries are also commonly associated with head and abdominal trauma with a blunt mechanism. The most common thoracic injury is rib fracture and mortality/morbidity increases as the number of ribs fractured increases. Mortality is most pronounced in the elderly where there is a 19% increase in mortality with each additional rib fracture.² Penetrating trauma accounts for the majority of deaths related to thoracic trauma but overall 85% of penetrating trauma to the chest can be managed with a chest tube. Regardless of the mechanism or obvious injuries one should always proceed with a systematic approach to the trauma patient, via Advanced Trauma Life Support (ATLS).

INITIAL IMAGING

The initial imaging in the trauma bay for suspected chest trauma is the screening chest X-ray (CXR) and the extended FAST (eFAST) examination. The CXR is typically a supine anteroposterior (AP) single film that helps the clinician determine if there are any bone fractures (ribs/clavicle/scapula), mediastinal hematoma (widened mediastinum >8 cm, loss of aortic knob, loss of aortopulmonary window, depression of left mainstem bronchus >110 degrees, deviation of nasogastric tube, apical cap, or tracheal deviation), pneumothorax, hemothorax, lung contusions, elevated diaphragm, large diaphragmatic rupture, or confirm position of endotracheal tube/any central lines in internal jugular or subclavian positions.³ If the spine is cleared then an upright AP film may be obtained, which increases sensitivity for hemothoraces and pneumothoraces. These films are often limited due to movement, clothing, backboards, or inadequate exposure but serve as reasonable screening image.

The FAST (Focus Assessment with Sonography for Trauma) has become a standard adjunct in the trauma bay. ATLS⁴ now has a module focused on the FAST examination and therefore, all physicians or advanced practitioners who care for trauma patients should become familiar with how to perform the FAST examination. The FAST examination views include the right upper quadrant, left upper quadrant, pelvic view, and the pericardium. For the purposes of this chapter the pericardial view is the view that will demonstrate hemopericardium. Hemopericardium is typically the result of penetrating trauma to the heart but may also be due to blunt rupture of the heart.⁵ Rozycki et al.⁶ used the FAST examination to determine if there was pericardial fluid in 1,540 patients with truncal injuries, with 100% sensitivity and 99.3% specificity. The eFAST includes the evaluation of lung to determine presence or absence of a large pneumothorax and evaluation for hemothoraces. The sensitivity of ultrasound to detect a pneumothorax is approximately 90% and is more sensitive than the screening supine CXR.⁷

Computed tomographic scans (CT scans) are often employed after the secondary survey and provide important information. They are highly sensitive for hemo/pneumothoraces, bone fractures, vascular injuries, and lung contusions/lacerations. CT scans are typically performed with intravenous contrast to better visualize vascular injuries and lung parenchyma.

COMMON INJURIES

Rib Fractures

The most common injury in thoracic trauma is the rib fracture. There is a spectrum of injury patterns ranging from single nondisplaced rib fractures to large flail segments with severe displacement. There are two general patterns of injury related to age and degree of flexibility of ribs. The younger population has innately more mobile/flexible ribs and therefore requires a higher force to create fractures. This higher force also translates to a higher degree of underlying lung contusion. The older population with more brittle ribs requires less force to fracture the ribs and therefore may not have as severe of an underlying lung contusion. The diagnosis is usually made by initial physical examination (tenderness and chest wall paradoxical movement for flails) and CXR (Fig. 24-1). However, CXR only visualizes 30% of rib fractures. CT scan is extremely sensitive for rib fractures and also allows one to quantify any associated hemothorax/pneumothorax.

Flail chests is defined as three or more segments of consecutive ribs broken in two or more places. These segments move independently and may exhibit a “mechanical” flail which is the paradoxical movement of the flail segment. As the patient inspires and expands the chest to produce a negative pressure, the flail segment is pulled toward the lung. The opposite occurs during expiration and the flail segment bulges outward (Fig. 24-2). The respiratory compromise that occurs in the face of a flail segment is multifactorial; (1) underlying lung contusion, (2) pain with respirations, and (3) mechanical disadvantage. The pain and the contusion are the most influential on clinical outcomes when compared to the mechanical disadvantage.

Figure 24-1. Rib fractures on CXR.

Treatment

2 The most important aspect of care for rib fractures is pain management. The majority of complications are directly related to lack of pain control. There are multiple studies suggesting that thoracic epidurals are superior to intravenous narcotics for treatment of pain related to rib fractures.^{8,9} Pain relief can also be provided by intercostal blocks, paravertebral blocks, or lidocaine patches but these methods are not as effective as administration of thoracic epidural analgesia. An aggressive pain management program will allow the patient to be more mobile and promote good pulmonary toilet to remove secretions and improve expansion of the lung.

There are two randomized clinical studies comparing surgical repair of ribs (open reduction and internal fixation) versus mechanical ventilation alone.^{10,11} Both studies suggest a benefit in surgical repair in terms of days on the ventilator, pneumonia, and function at 6 and 12 months. Therefore, it is recommended for those with large flail chest (five or more ribs) on mechanical ventilation without a reason for prolonged intubation, that is, severe traumatic brain injury, to undergo rib fixation. This conclusion has also been supported by other nonrandomized trials.^{12,13} There are multiple types of rib

fixators available (Fig. 24-3) and no repair has proven superior. The majority of ribs repaired are number 4 to 9, approached via a thoracotomy incision (Fig. 24-4).

Figure 24-2. Pathophysiology of flail chest. **A:** Inspiratory phase: chest wall collapses inward, causing air to move out of the bronchus of the involved lung into the trachea and bronchus of the uninjured lung, causing a shift of mediastinum to the uninjured side. **B:** Expiratory phase: chest wall balloons outward so that air is expelled from the lung on the uninjured side and enters the lung on the involved side with an associated shift of mediastinum to the involved side.

Figure 24-3. Rib fixation with plates.

For patients who do not have large flail chests, which is the majority, the indications for rib fixation remain elusive. In general, the author's approach is to consider rib fixation for any patient with three or more ribs fractured with severe displacement (more than the width of a rib). The patient population that would significantly benefit from fixation is unclear and at this point the decision is made on a case-

specific basis.

Pneumothorax

Pneumothoraces can be classified into three subtypes: occult, simple, and tension. The initial diagnosis can be made with physical examination by auscultation. Auscultation is the first diagnostic test performed during the “Breathing” portion of the primary survey. One should be sure to auscultate the chest in two primary positions (bilateral midaxillary lines). This provides the examiner with the greatest specificity since these positions represent the most distant portions of the hemithorax from the contralateral hemithorax. Anterior positions can often be falsely positive for breath sounds secondary to overlapping pleura or transmitted sounds from the contralateral side.

Figure 24-4. Rib Fixation with plates (photo).

The next most commonly used diagnostic test is ultrasound during the extended FAST examination looking specifically for lung sliding. Lung sliding has a high sensitivity and specificity (78.6% and 98.4%)¹⁴ for the presence or absence of a pneumothorax as described above. The standard of care in the trauma bay is upright (if spine is cleared) or supine AP X-ray if the spine is not cleared. Although radiographs are less sensitive than ultrasound for small pneumothoraces they are used to screen for other associated injuries as described above.

An occult pneumothorax is one that is seen on CT scan (which is the most sensitive test for pneumothorax) but not seen on CXR (Fig. 24-5A, B). Subcutaneous emphysema is a sign that should alert the clinician to pneumothorax (Fig. 24-6). A simple pneumothorax is one that is seen on either CT scan or CXR but is not associated with hemodynamic compromise. Those patients with a pneumothorax and hemodynamic compromise must be considered a tension pneumothorax until proven otherwise. Tension pneumothorax is not a radiologic diagnosis but rather a clinical diagnosis. A tension pneumothorax is a pneumothorax that has progressed to the point that the mediastinum is shifted compromising in-flow to the heart. Kinking of the great vessels is the pathophysiology that leads to an acute decrease in cardiac output and shock. Unless tension is released the patient will die. Signs and symptoms of a tension pneumothorax include; shortness of breath, dyspnea, tachypnea, hypotension, distended neck veins, and tracheal deviation (away from the site of injury). If any of these signs are present immediate decompression is necessary.

Treatment of Pneumothorax

If the patient is unstable and a tension pneumothorax is suspected needle decompression may be considered. A large-bore, 14- to 16-gauge angiocatheter is inserted into either the anterior second intercostal space in the midclavicular line or the fifth intercostal space in the midaxillary line. There is some cadaveric data that suggests that the fifth intercostal space in the midaxillary line has the least distance from the skin to the pleural cavity and therefore, may be superior to the anterior position.¹⁵ This converts the tension pneumothorax to a simple pneumothorax which can subsequently be drained with a proper tube.

3 If one has access to a chest tube quickly there is no need to perform a needle decompression. Classically an open chest tube in the zone of safety may be placed. The zone of safety is outlined by the pectoralis major lateral border, the nipple line in men (two fingerbreadths above the inframammary

fold, women), and the anterior border of the latissimus dorsi. The triangle formed by these borders is a guide for the practitioner for placement of the chest tube (Fig. 24-7). If the tube is placed too far caudal it can easily enter the abdominal cavity. A standard 28-Fr chest tube may be placed as there is no difference between a 36 Fr and 28 Fr in ability to adequately drain the chest of either pneumothorax or hemothorax.¹⁶ In those patients with a pure pneumothorax a 14-Fr pigtail catheter is also acceptable and may be superior given the significantly less pain/discomfort of the tube as described in a randomized clinical trial.¹⁷ Pigtail catheters are placed using a Seldinger technique in the identical areas as the open chest tube technique.

For those patients who have a simple (or occult) pneumothorax one should be guided by progression of the pneumothorax or the development of signs/symptoms of cardiopulmonary compromise. In a series of 146 patients with pneumothoraces, 90% of pneumothoraces that were 3.5 cm in widest dimension were successfully observed. This holds true in the intubated patient on positive pressure ventilation as well.¹⁸ Therefore, as a general rule, if the patient is stable one should repeat the CXR and if the pneumothorax is significantly larger (definition of significantly larger varies) or if the patient becomes symptomatic then a tube should be placed to reexpand the lung. No longer is there a need for a mandatory chest tube for pneumothoraces, even for those on positive pressure ventilation.

Figure 24-5. A: AP CXR in trauma bay with no evidence of pneumothorax. B: Occult pneumothorax seen on CT scan C: Measurement of largest air pocket in a line drawn perpendicular to the chest wall.

Figure 24-6. Subcutaneous emphysema.

Figure 24-7. Zone of safety.

Pulmonary Contusion

In the presence of flail chest or multiple rib fractures one may observe a significant decrease in the $\text{PaO}_2/\text{FiO}_2$ ratio. Rather than a function of the mechanics of the chest wall this is most consistently a result of underlying lung contusion. Lung contusion is the extravasation of blood into the interstitial space of the lung parenchyma. Bleeding may extend to the alveolar space as well in severe cases.

Treatment

The treatment for lung contusion complicated by hypoxia is primarily supportive, with administration of positive end-expiratory pressure (PEEP). PEEP may be applied either noninvasively (face mask) or through an endotracheal tube. In a small study, it was found that 100% of patients who had five or more ribs fractures, two-thirds or more of lung affected by contusion, and a decrease in mental status ($\text{GCS} \leq 14$) required intubation.¹⁹ Intubations did not necessarily occur on the first day but often on the second day. Therefore, it is important to identify patients at risk for intubation and place them in a higher level of care. Other key aspects of care include minimizing intravenous crystalloid fluids, early mobilization, and encouraging cough/deep breathing.

Hemothorax

Initial imaging is the screening CXR. This x-ray is often a supine AP film that may make the diagnosis of a hemothorax challenging. In the supine film the blood layers in the posterior recess of the hemithorax and the x-ray may appear hazy when compared to the contralateral side. In the face of a large hemothorax the x-ray can appear as a white out. Ultrasonography during the extended FAST

examination has a high sensitivity for detecting a hemothorax.

The causes of hemothorax are varied, the most common being rib fractures/intercostal muscle to intercostal artery laceration, pulmonary laceration, or cardiac injury with communication to the pleura via injury to the pericardium. The urgency of the treatment is dictated by the physiologic state of the patient with rapid control of hemorrhage is the first priority.

4 Hemothoraces associated with hemodynamic instability or those that drain >1,500 cc immediately or >200 cc/hour for >4 hours after placement of a chest tube should be taken directly to the operating room for exploratory thoracotomy. The size of chest tubes has decreased over time and contemporary data suggests that there is no difference in the ability of the 28-Fr versus the 36-Fr chest tube to effectively drain a hemothorax. Some have advocated a 14-Fr pigtail catheter for drainage of a hemothorax. In terms of chest tube position, there is little convincing evidence to suggest that the position of the chest tube, anterior or posterior, makes a difference in the ability of the tube to drain a hemothorax.²⁰ This is likely a result of the pleura being a closed system and therefore, suction applied to one area will apply equal amounts of pressure to other areas of the pleural space. The liquid component of the hemothorax will be drained from any position. Clotted blood will not be effectively drained even if the tube is in the middle of the clot. In general, patients with a moderate to large volume hemothorax should be drained, approximately 300 cc when estimated using the following formula: Estimated volume (cc) = $d^2 \times l$, where d equals the greatest dimension in centimeters from the chest wall to the lung or mediastinum across the largest fluid pocket, and l is the craniocaudal height (number of axial slices on the CT scan $\times$ the thickness of those slices in centimeter).²¹

Retained Hemothorax

Retained hemothoraces may occur in 30% of the patients.²² A retained hemothorax is defined as hemothorax that persists despite an attempt at drainage. If the hemothorax is not adequately drained in a 24-hour period it may be necessary to differentiate the hemothorax from atelectasis. A CT scan will help the surgeon differentiate between the two and allow one to calculate the amount retained.

If the amount is moderate to large there are two options; (1) early video-assisted thoracostomy to evacuate the clot or (2) tissue plasminogen activator (TPA) with or without DNAase. The key point is that early intervention allows the clot to be evacuated and prevent a fibrothorax from forming. Ideally, surgical drainage should be performed within 7 days to optimize the ability to successfully perform thoracoscopy.

Aortic Injury

Those patients with evidence of mediastinal hematoma on CXR, as described above, or those with a high-risk mechanism, that is, same-side motor vehicle collision (t-bone collision) should have a CT scan of the chest with intravenous contrast. CT scan has become the standard of care for diagnosis and classification of aortic injuries. Aortic injuries most commonly occur at points of fixation. These locations in decreasing order of occurrence include; (1) ligamentum arteriosum (just distal to the left subclavian artery), (2) diaphragmatic hiatus, and (3) root of the aorta (these usually die at the scene). The current classification of aortic injuries divides the extent of injury into four grades; (1) small intimal tear, (2) intramural hematoma (3) pseudoaneurysm (Fig. 24-8A,B), (4) periaortic rupture. The treatment of these injuries has evolved.

5 Small injuries are placed on aspirin for 6 months. Types 2, 3, and 4 are treated with placement of covered stent grafts via an endovascular approach. When compared to open clamp and sew repairs the incidence of paraplegia is much lower in the endovascular treatment group, which has resulted in its adoption as the contemporary standard of care (Fig. 24-9).²³ These injuries do not need to be repaired immediately as long as there is control of heart rate and blood pressure. The goal HR is <80 and goal systolic blood pressure is <110 mm Hg. This control is achieved with the administration of short acting beta-blocker (i.e., esmolol) followed by nitroprusside. The beta-blocker must precede the nitroprusside because of the possible tachycardic side effects of nitroprusside. Patients should have an immediate arterial line placed, esmolol begun and titrated carefully to achieve the target hemodynamic parameters. This allows time for other associated injuries to be managed, that is, head injury, intra-abdominal bleeding, severe pelvic fracture. Then in the following 24 to 48 hours as the initial resuscitation and urgent treatments are achieved, repair of the aorta may follow. For those with high-grade aortic injuries, repair should take a higher level of priority but remains balanced with other conflicting priorities.

Diaphragmatic Injuries

Injuries may be the result of either penetrating or blunt trauma. The average size of a diaphragmatic injury for penetrating trauma is approximately 2 cm and the average size of the injury for blunt trauma is 8 cm. In a 2015 review, there were 3,873 diaphragmatic injuries among the sample size of 833,309 giving an incidence of 0.46%.²⁴ Initial imaging begins with CXR and is often followed by CT scan. The sensitivity for diaphragmatic injuries on CT scan is approximately 70% (range is from 50% to 90%). For penetrating trauma CXR and CT scan have very poor sensitivities and one must maintain a high index of suspicion depending upon the trajectory of the knife or bullet. If there is a penetrating trauma to the thoracoabdominal region (nipple line to costal margin) particularly on the left side one should perform a diagnostic laparoscopy after a 24-hour window. This 24-hour window allows the surgeon to effectively exclude an associated hollow viscus injury since these patients would manifest as peritonitis prior to 24 hours.

Figure 24-8. A: Axial view of type III blunt aortic injury with pseudoaneurysm. B: Sagittal view of type III blunt aortic injury with pseudoaneurysm.

Treatment

Once the diagnosis is made the patient should be taken to the operating room for repair. In the case of the penetrating trauma patient who is undergoing a diagnostic laparoscopy the repair can proceed laparoscopically via the abdomen. For those with an acute rupture following blunt trauma the repair is usually undertaken via the abdomen in order to inspect abdominal organs for injury. For chronic hernia defects, one may consider repairing from the chest via a thoracotomy or via video-assisted thoracoscopy.

Figure 24-9. Aortic stent graft for blunt rupture.

The repair is with a nonabsorbable suture in either an interrupted or running fashion. The classic repair is with an interrupted horizontal mattress but can be a figure of eight or running suture. The repair must be air tight and a chest tube is usually placed at the time of the repair. It is important to lavage the chest and ensure complete evacuation of any hemothorax via the hole in the diaphragm. In patients where primary repair of the diaphragm is not possible due to tissue loss a mesh (synthetic or biologic) may be used or the diaphragm can be sown to a lower rib, in essence transposing it to a slightly lower position to achieve closure of the hemithorax.

Cardiac

Lacerations can occur with either penetrating or blunt mechanisms. The most common chamber affected with penetrating injury is the right ventricle since it has the largest anterior surface area. The right atrium is the most common chamber that ruptures from blunt mechanisms because of its thin wall. The diagnosis of hemopericardium is usually made via the bedside FAST examination. The FAST examination is 95% sensitive and specific for hemopericardium, and is an important adjunct in the trauma bay. Hemopericardium is diagnosed by ultrasound but tamponade is diagnosed by the combination of hemopericardium and hypotension. The presence of distended neck veins, hypotension, and hemopericardium defines cardiac tamponade and should be treated emergently.

Treatment

If a patient is deteriorating (with loss of consciousness) or has lost vital signs then an ED thoracotomy is indicated. This provides quick access to the pericardium and allows the surgeon to decompress the tamponade, gain control of the hole and potentially repair the injury in the trauma bay. If the patient is awake or vital signs are not quickly deteriorating then an emergent transport to the operating room is preferred. There is very limited role for pericardiocentesis in the acute trauma scenario, given the difficulties in evacuating clot from the pericardium. A pericardial window is a diagnostic test and is restricted to those patients who have a possible confounding issue and are stable, that is, HIV-positive patients with chronic pericardial effusions. Otherwise, a positive pericardial FAST mandates surgical exploration via a sternotomy or thoracotomy.

It is important to understand that in cardiac tamponade when the patient is placed under general anesthesia and placed on positive pressure ventilation the subsequent drop in preload may cause the patient to lose vital signs. Therefore, the surgical team must be ready to quickly perform a median sternotomy. The patient should be prepped and draped from the chin to the thighs, in case there is the need to enter the neck or the abdomen. Once the patient is prepped and draped then anesthesia is induced and the operation commences. This allows the team to be ready with the sternal saw and equipment prior to induction just in case the patient loses vital signs.

Once in the chest via the preferred incision, median sternotomy, the pericardium is opened and the injury identified. The injury can usually be controlled with a finger or two. Other adjuncts are then employed to close the wound, that is, skin stapler, Foley catheter (careful not to rip the thin right ventricle with the balloon), or two stay sutures on either side of the injury that are crossed to close the wound. Once temporary control is obtained one may then place additional sutures which are usually 3-0 silk or prolene. It is helpful to ask for a suture with a large needle. The hole is then closed with or without pledgets in an interrupted fashion. One must take note of the relationship of the injury to the coronary vessels. If the injury is juxtaposed to a coronary vessel, one should perform a horizontal mattress and pass the needle deep to the coronary artery. If the coronary vessel is injured by the trauma it must be bypassed or repaired if it involves the proximal two-thirds. If the distal third of a coronary is involved it is possible to simply ligate the artery.

Postoperative echocardiography should be performed to evaluate the function of the valves to ensure there is no significant injury to valvular function.

Blunt Cardiac Contusion

There is a spectrum of blunt cardiac contusion, better named blunt cardiac injury. Injuries may cause mild dysrhythmias or lead to wall rupture ([Fig. 24-10](#)) and death. Any patient that undergoes a rapid deceleration is at risk of having a traumatic blunt cardiac contusion. These patients are screened with a 12-lead ECG and if completely normal one can rest assured that there is no significant contusion. If the patient has any dysrhythmias including sinus tachycardia serial troponin levels will provide the additional sensitivity to diagnose contusion.

Treatment

These patients are placed on telemetry and observed. If ST segment changes occur a cardiac catheterization is necessary to rule out coronary dissection. If the patient is unstable but with normal ST segments an echo should be performed to identify structural injuries, that is, valve damage or septal defects.

Open Pneumothorax

In circumstances where there is a loss of a portion of the chest wall the normal negative pressure pleural space is lost. The chest wall defect is usually secondary to a high-velocity bullet or close range shot-gun blast. Due to the intrinsic nature of the lung parenchyma to collapse, there must be negative pressure in the chest wall to allow for reexpansion. In an open pneumothorax (sucking chest wound) the lung collapses and the patient has difficulty with ventilation.

Treatment

As a temporary measure, perhaps during transport, a partially occluding dressing can be applied. This dressing is sealed in a way that allows air to escape from a corner of the dressing while preventing atmospheric air from entering the pleural space. However, if encountered in the trauma bay or the operating room the trauma surgeon should close the defect and place a chest tube in a separate space. The chest tube will create the negative pressure required to reexpand the lung with the defect closed. If the defect is large a rotational flap may be necessary to close the defect or the chest wall may require reconstruction with mesh.

Tracheobronchial Injury

Injury can occur from either blunt or penetrating mechanisms and usually presents with a large pneumothorax and air leak. More proximal intrathoracic injuries can be easily visualized via bronchoscopy. At times the patients may be difficult to ventilate due to large air leaks. In rare cases there may be the need for selective lung ventilation with a bronchoscopically placed bronchial blocker or may even require extracorporeal membrane oxygenation (ECMO).

Treatment

The majority of intrathoracic injuries are to the right mainstem bronchus and therefore a right posteriolateral thoracotomy is the best approach. The location of the injury on bronchoscopy will provide direction for surgical exposure. Once exposed the bronchus or trachea can be primarily repaired using a 3-0 absorbable suture. Chest tubes are placed and extubation is guided by the underlying lung contusion and hypoxia. Ideally, these patients should be taken off positive pressure ventilation as soon as possible, even immediately postoperatively.

Figure 24-10. Blunt cardiac rupture/contusion.

Thoracic Esophageal Injury

Esophageal injuries are secondary to penetrating trauma. A blunt rupture of the esophagus is exceedingly rare. The signs and symptoms of an acute injury are nonspecific and include hematemesis and chest pain. If the trajectory of the knife or gun-shot wound is such that it crosses the midline, the mediastinum must be evaluated. If the patient is unstable from a thoracic gun-shot wound a rapid trip to the operating room is warranted for exploration and hemorrhage control. If the patient is stable one may perform imaging studies to evaluate the esophagus.

The initial imaging study is a CT scan of the chest with IV contrast to better delineate the track of the missile (Fig. 24-11A). Secondary signs of an esophageal injury may be present including pneumomediastinum, pleural effusion, or mediastinal hematoma. If the missile track is in close proximity to the esophagus (<2 cm) then additional imaging with a water-soluble followed by a barium-contrast study is warranted. The water-soluble contrast is used first in case there is a large leak (Fig. 24-11B). If no obvious leak is identified then the water-soluble contrast should be followed up with a barium study to increase the sensitivity for a small leak. If the barium esophageal imaging is negative one can be assured there is no full-thickness injury to the esophagus. If an injury is identified as an esophageal leak urgent exploration is necessary to minimize contamination of the chest. There is a direct correlation between time to repair and morbidity/mortality, therefore any delay must be minimized.

Figure 24-11. A: Tract of bullet coursing to posterior mediastinum. B: Contrast leaking from an injury to the esophagus.

If the distal one-thirds of the thoracic esophagus is injured a left thoracotomy is the approach of choice. If the proximal two-thirds is involved then a right thoracotomy is performed, which allows one to dissect the esophagus up to the thoracic outlet since the aortic arch is not obscuring the view. Once the esophageal injury is identified, it should be debrided and repaired in a full-thickness single layer. The repair should be buttressed with either a pedicled intercostal muscle flap or a pleural patch. Some have used a tongue of omentum for distal esophageal repairs. Of note, single lung ventilation is necessary to adequately visualize the injury and ensure a safe repair.

EMERGENCY DEPARTMENT THORACOTOMY VERSUS OPERATIVE THORACOTOMY, TIPS/TRICKS

ED thoracotomy is a procedure done to gain primary vascular control of an injured vessel, it also allows one to open the pericardium, perform internal massage, relieve cardiac tamponade, repair cardiac injury, gain control of the pulmonary hilum, and clamp the aorta if necessary. The ED thoracotomy is a

left anterolateral thoracotomy (Fig. 24-12). The survival from ED thoracotomy is as high as 60% in victims of penetrating trauma that arrive in the trauma bay with a palpable pulse. The survival decreases to about 4% if the patient arrives without a pulse, assuming a less than 15-minute cardiac arrest time. In blunt trauma the odds of regaining a blood pressure in those who lose vital signs in the trauma bay is about 4% but drops to 0.2% if lost in the field. For these reasons the generally accepted indications for an ED thoracotomy in penetrating trauma is if the patient loses vital signs in the trauma bay or within 15 minutes of arrival. For blunt trauma, the only accepted indication is patients who lose vital signs in the trauma bay. ED thoracotomy is a futile maneuver (and should be avoided) in patients who suffer cardiopulmonary arrest, although some advocate ED thoracotomy if the patient loses signs within 10 minutes of arrival.

Figure 24-12. Left anterolateral thoracotomy incision.

The indications for a formal operative thoracotomy are if the initial chest tube drains $>1,500$ cc of blood or >200 cc/hr $\times$ 4 hours. The other indication is if there is ongoing hemodynamic instability with continued chest tube drainage.

Control of an intercostal artery can be difficult if low in the chest and posterior. At times it may be necessary to encircle the rib proximal and distal to the bleeding vessel to compress the vessel indirectly. This suture can be absorbable or even brought out through the full thickness of the chest wall and cut in 48 hours. At times one may be dealing with a deep hole from a gun-shot wound into the musculature of the posterior chest wall. Under these circumstances aggressive and tight packing may suffice or a Foley catheter may be placed in the tract and inflated to tamponade the bleeding. The Foley may even exit the chest wall via a separate stab incision and be deflated 24 to 48 hours later and removed while the patient is observed for recurrent bleeding.

The other common injury that may be found on exploration is a laceration of the lung. It is important to understand that bleeding from the track of a penetrating trauma must not be closed superficially. Closing the entrance or exit holes may simply cause more bleeding into the bronchi or allow air to embolize from the bronchi to the pulmonary venous system. Patients will die from cardiac arrest from air emboli that enter the coronary vessels. Instead the pulmonary tract should be opened (tractotomy) with either clamps or GIA stapling devices. This opens the tract where the raw surface area can be oversewn or stapled while saving lung tissue. Peripheral lesions can simply have wedge resections performed.

CONCLUSION

Thoracic injuries are a common entity with rib fractures being the most common injury. A careful and systematic approach to the trauma patient is key to uncovering significant thoracic injuries. Life-threatening injuries, that is, massive hemorrhage, tension pneumothorax, or cardiac tamponade must be identified within the trauma bay and treated without delay.

Chapter 25

Abdominal Trauma

Kenji Inaba, Elizabeth R. Benjamin, and Demetrios Demetriades

Key Points

- 1 Clinical examination is the cornerstone of the diagnostic workup after blunt abdominal trauma and any patient with peritonitis or instability with a positive FAST requires immediate laparotomy. CT is a high-yield diagnostic modality for the intra-abdominal contents with high degree of sensitivity and specificity for clinically significant injuries.
 - 2 For stable, evaluable patients without peritonitis or evisceration after penetrating abdominal trauma, selective non-operative management is an acceptable treatment option. For those undergoing non-operative management of a gunshot wound, CT scanning is essential. For both stab wounds and gunshot wounds, close clinical observation is utilized to detect those patients with an occult injury that will ultimately require laparotomy and repair.
 - 3 Rapid access to an operating room with immediate access to the instrumentation, consumables and support services such as the blood bank and radiology are required for the successful treatment of patients with abdominal trauma.
 - 4 Standard positioning is supine, however, for injuries in stable patients where the rectum or perineum is at risk, lithotomy may be utilized. The initial incision is usually a midline laparotomy. Extension into the subcostal regions and across the inguinal ligament or into the thoracic cavity may be required to facilitate exposure.
 - 5 Damage control laparotomy, which consists of rapid bleeding and contamination control, followed by temporary closure and resuscitation with delayed definitive repair of injuries should be considered for any patient who is physiologically depleted, has a burden of injury which will result in compromise if definitive repair is attempted, or has an injury profile beyond the scope of the surgeon or facility skillset.
 - 6 Abdominal compartment syndrome is after trauma laparotomy and all patients should be monitored closely with bladder pressures in the recovery area. Any elevation in the intra-abdominal pressures warrants consideration of decompressive laparotomy.
 - 7 Angioembolization is an important adjunct for patients who are undergoing damage control surgery and may be of particular benefit for patients with ongoing bleeding from complex hepatic trauma.
-

INTRODUCTION

For patients who have sustained a stab wound (SW), gunshot wound (GSW), or blunt multisystem injury, the abdomen remains a high-risk cavity with the potential to hide occult but life-threatening injuries. Unlike the extremity or neck for example, where bleeding occurs externally, for the abdomen, significant bleeding and enteric spillage can occur with minimal symptoms until late. In patients presenting after both blunt and penetrating traumas, injury to the abdominal contents is common. In the National Trauma Data Bank, the largest repository of trauma registry data that exists in the United States, from 2008 to 2012, of the approximately 3,146,401 patients entered, 10.6% had an abdominal injury.

Broken down by regional abbreviated injury scale (AIS), 34.0% of these had an AIS 1, 31.4% an AIS 2, 21.8% an AIS 3, 9.9% an AIS 4, and 2.9% an AIS 5 injury. This injury severity breakdown for all patients was consistent with the data seen for blunt trauma. In comparison, when penetrating injuries were examined, whereas only 9.6% of blunt trauma patients had an abdominal injury with 33.5% having an AIS ≥ 3 , a full 25.2% of penetrating patients had an abdominal injury with 39.7% of these having an AIS ≥ 3 .

Abdominal injuries are therefore common and a systematic approach to the rapid diagnosis and

treatment of these injuries is essential. This chapter will provide a pragmatic approach to the patient with abdominal trauma, focusing on the acute resuscitation, diagnosis, and treatment of clinically relevant injuries to the abdominal structures.

BLUNT INITIAL EVALUATION AND DIAGNOSTICS

Resuscitation

For the patient that sustains abdominal trauma, unlike the extremity, where a tourniquet can be placed, there are currently no validated prehospital methods for direct or indirect hemorrhage control. With the increasing interest in resuscitative endovascular balloon occlusion of the aorta,¹ in the appropriate clinical setting with trained personnel, this procedure could theoretically be performed in the prehospital setting. Experimental work looking at the use of abdominal insufflation with air or foam also shows some promise but is not yet ready for clinical implementation at this time. Rapid transport to definitive care therefore remains the primary goal. The general principles of resuscitation that apply to all trauma patients as outlined elsewhere in this textbook should be followed. Specific to patients with abdominal trauma, whenever possible, venous access should be gained in the upper limbs or torso. Resuscitation through a femoral central venous catheter is suboptimal as the return of blood products into the systemic circulation is compromised if the patient has an injury to the iliac system or vena cava. In the resuscitation area, once the diagnosis of an intra-abdominal injury requiring operative repair has been made, travel to the OR should take precedence over continued resuscitative efforts which can be continued concurrent to definitive hemorrhage control.

Diagnostics

1 The diagnostic workup of a blunt multisystem injury patient is often more difficult than for a penetrating injury patient. The following discussion focuses on the isolated abdominal trauma patient however, practically, for most patients the remainder of the torso must also be considered. In general, the most practical approach to the patient in the resuscitation area depends on hemodynamic status. Patients can be categorized into those that are arresting, unstable, or stable.

For any arresting patient, if the decision to intervene is made, airway control, venous access with blood product infusion, and resuscitative thoracotomy with concurrent right chest tube insertion are the immediate priorities. The outcomes for resuscitative thoracotomy performed for traumatic arrest due to blunt trauma are poor,² especially if the source of hemorrhage is in the abdomen, and at many centers, would not even be considered. Survival to discharge and organ donation are possible however, and at our center, thoracotomy is performed liberally. If a resuscitative thoracotomy is performed, and the primary source of hemorrhage is in the abdomen, aortic cross-clamping is designed to mitigate intra-abdominal blood loss. If the procedure is successful and a perfusing rhythm is regained, there is no role for any imaging or further workup. The patient should be taken immediately to the OR for laparotomy and definitive injury management.

For the unstable patient, aggressive resuscitation with blood products should be initiated immediately, and the patient will either stabilize, in which case a complete workup can be performed as described below, or they will arrest, as discussed above or they will remain unstable. If they remain unstable despite resuscitative efforts, bilateral diagnostic chest tubes should be inserted if a chest x-ray (CXR) is not immediately available. Concurrent with the ongoing resuscitation, a focused assessment with sonography in trauma (FAST) should be performed. If free abdominal fluid is visualized, the patient should immediately be taken to the OR and a laparotomy should be performed. If the FAST is negative, a confirmatory diagnostic peritoneal aspirate (DPA) looking for gross blood should be performed. If this is positive, the patient undergoes laparotomy. If negative, alternative sources for the hemorrhage are sought. It is possible that the source of hemorrhage is a contained retroperitoneal vascular injury which would be missed by both DPA and FAST however, for blunt trauma, in the absence of a pelvic fracture, this would be extremely rare.

In the stable patient, a complete diagnostic workup can be completed. This begins with an external examination for any soft tissue evidence of injury. A seatbelt sign for example has been associated with an eightfold increase in the incidence of intra-abdominal injuries, impacting both the solid organs and hollow viscus.^{3,4} While not sufficient to warrant mandatory laparotomy, a very low threshold for imaging with CT should be maintained and the patient should undergo a mandatory period of observation. With this mechanism, the seatbelt can cause a “bucket-handle” type injury (Fig. 25-1)

where the mesentery is sheared away from the more elastic bowel wall causing ischemia. Clinical evidence of the ischemic GI tract injury can take hours to manifest and close observation is warranted.

If on initial examination, the patient already has peritonitis, in the setting of trauma, immediate laparotomy should be performed. This is a high-yield indication for operation. Although data were accrued in penetrating trauma, the urgency of peritonitis was made clear in a study examining 139 patients who were hemodynamically stable with peritonitis as the sole indication for operation. Of these, 97% had an intra-abdominal injury, with 11% having between 750 and 1,500 mL and 7% having >1,500 mL of blood on opening with 25% sustaining intraoperative hypotension and 39% requiring blood transfusions despite being hemodynamically normal at presentation.⁵

Figure 25-1. Bucket handle–type injury of small bowel.

For patients without peritonitis, the initial imaging modality is FAST. Because cardiac rupture causing an effusion is so rare in blunt trauma patients presenting alive to the hospital,⁶ the abdominal windows are of primary importance after blunt trauma. The presence of free fluid is assumed to be blood. The presence of free fluid should trigger additional imaging with CT. For blunt trauma, there is no role for plain radiographs of the abdomen. In unstable patients, a pelvic x-ray can identify a potential source of ongoing blood loss and should be performed early in the resuscitation bay. For the stable patient, a pelvic x-ray is unnecessary especially if the patient is to undergo CT as it is unlikely to impact management. Although specific trauma protocols vary between institutions, CT scans should be performed with IV contrast. PO contrast is not required for the initial CT. A baseline creatinine level for all patients and a pregnancy test in females of child-bearing age should be obtained prior to the test. In general, a CT should be considered in the stable patient when there is external evidence of significant force transfer to the abdomen such as a seatbelt sign, or with free fluid on FAST or when there is significant abdominal tenderness on examination. Mechanism as a sole criterion for deciding which patients require CT scanning is unreliable, but a high-energy mechanism is often considered when making this decision. For the asymptomatic patient with a negative FAST who is fully examinable, cooperative, and can be observed, CT can be omitted. Based on the CT results, patients can be categorized into three groups, those with no injury, those with an injury, and those with an equivocal finding. If the patient has a fully adequate CT demonstrating no abnormalities, the likelihood of a clinically significant injury is extremely low and the patient can be prepared for discharge once the remainder of the body areas is cleared. For patients with a CT that demonstrates injury, the nature of the injury will determine management. Any hollow viscus injury including the GI tract or bladder, will require operative repair. For solid organ injuries, the indications for operative management will depend on the extent of injury, the physiologic status of the patient including comorbidities, and their tolerance for blood loss and associated injuries. In general, the majority of solid organ injuries can be successfully managed non-operatively.^{7,8} In centers where there is access to interventional radiology, endovascular solutions, such as stenting or embolization and percutaneous management of complications such as a biloma can also be used as an adjunct to non-operative management. This will be further elucidated in the following organ-specific sections. This then leaves the patient with equivocal findings of a hollow viscus injury on CT. Equivocal findings would include subtle findings such as mesenteric fat stranding, free fluid without solid organ injury, and bowel wall thickening. These patients should be observed clinically, ideally by a single provider and collateral evidence of injury such as the WBC count, heart rate, temperature, and abdominal examination are used to detect worsening, indicative of a hollow viscus injury requiring operative intervention. The exact period of time required for observation is

unknown, however, it is expected that a patient who is improving at 24 hours has a low likelihood of a clinically significant missed injury.

PENETRATING INJURY – INITIAL EVALUATION AND DIAGNOSTICS

General Approach to Penetrating Abdominal Injury

Following the experience of World Wars I and II, with the high rates of destructive injuries, penetrating abdominal trauma was historically treated with universal surgical exploration. Starting in the 1960s, with SWs, followed by GSWs, this paradigm began to shift.⁹⁻¹¹ Patient selection for operative versus non-operative management based on the clinical picture and radiologic evidence began to evolve. With improved access, and quality of the images and the growing body of evidence regarding the potential morbidity of nontherapeutic operations, contemporary evidence now supports a non-operative approach to the management of penetrating abdominal trauma in select circumstances.¹²

2 The balance between prompt surgical management of traumatic injury and avoiding unnecessary operation remains a central diagnostic and management challenge in penetrating abdominal injury. Patients who present *in extremis*, with hemodynamic instability, peritonitis, or are unevaluable mandate immediate operation. For the remaining patients, the practice of universal exploration would result in a high rate of nontherapeutic laparotomy. Although mortality after negative trauma laparotomy is low, morbidity attributed to negative laparotomy is as high as 20%.^{13,14} In addition, late complications including hernias and bowel obstructions are likely underreported given the challenges of long-term follow-up. Finally, not only is there a decrease in patient-centered outcomes, from a trauma resource utilization viewpoint, negative laparotomy is associated with an increase in unnecessary operative costs and hospital length of stay.^{13,15-17} The introduction of selective non-operative management of penetrating abdominal trauma has been shown to result in a tangible cost savings.¹⁸

Although a subset of patients with penetrating abdominal trauma will ultimately require exploration, a significant number can be managed without operative intervention and thus be spared the potential morbidity and mortality of a negative laparotomy. In a retrospective analysis of abdominal SWs, mandatory exploration was associated with a negative laparotomy rate of 37%.¹³ A Western Trauma Association Multicenter Study including 359 patients with anterior abdominal SWs found that 64% of patients did not require laparotomy.¹⁹ The need for laparotomy is even lower after SWs to the back with only 15% of patients noted to have clinically significant injury.²⁰ GSWs to the abdomen are more likely to require operative exploration, but the presence of gunshot injury alone does not necessitate mandatory laparotomy. In an analysis of 1,856 patients with abdominal GSWs, had a policy of mandatory laparotomy been employed, 47% of patients would have undergone an unnecessary laparotomy.¹⁸ Similar to SWs, posterior and transpelvic injuries are less likely than anterior injuries to require exploration.^{18,21-22}

Indications and Contraindications to Selective Non-operative Management

In the modern era of selective non-operative management of abdominal trauma, several absolute indications for operative intervention remain. Hemodynamic instability in the setting of penetrating abdominal trauma requires laparotomy. In the hemodynamically stable patient, physical examination remains critical to patient triage, and peritonitis is an absolute indication for laparotomy. Although soft tissue injury can cause local tenderness, diffuse peritonitis after penetrating abdominal trauma is associated with a 97% chance of intra-abdominal injury at laparotomy.⁵ Given the central role of physical examination in patient triage, unevaluable patients including those with concomitant head or spinal cord injury or those undergoing urgent nonabdominal operations are not candidates for selective non-operative management. Although not an absolute contraindication to selective non-operative management, patients with omental or visceral evisceration after penetrating abdominal trauma should be strongly considered for operative intervention. Significant intra-abdominal injury is present in 46% to 85% of patients with omental evisceration, and even higher rates with visceral evisceration.^{17,19,23,24}

Peritoneal penetration alone after penetrating trauma is not an absolute indication for operative exploration. For this reason, invasive evaluation including diagnostic laparoscopy for the sole purpose of determining peritoneal violation is not indicated.

Diagnostics

Radiologic imaging is a key component of the diagnostic workup of patients who have sustained penetrating abdominal trauma, especially those undergoing a trial of non-operative management. In hemodynamically stable evaluable patients without peritonitis, a detailed evaluation of the external wounds and retained fragments using plain radiographs is imperative to plot missile trajectories. External wounds do not always correspond to internal injury and, especially in the setting of multiple missiles, trajectory may be misleading from external wounds alone. For example, an abdominal GSW may have a cranial trajectory resulting in a mediastinal injury. Alternatively, paired lateral abdominal wall bullet wounds may represent a superficial tangential trajectory or two separate transabdominal injuries with retained missiles. In both scenarios, management will change significantly based on the internal trajectory.

FAST examination is a central component of the early assessment after blunt trauma. The utility of this imaging modality in penetrating trauma, however, is less uniformly accepted. The primary use of the FAST examination in penetrating abdominal trauma is to evaluate for pericardial fluid as a marker of cardiac injury. Especially in the setting of an unknown missile trajectory, the cardiac FAST is a critical component of the initial trauma evaluation. A positive cardiac FAST after penetrating trauma mandates immediate median sternotomy. For the intra-abdominal fluid windows, while the FAST examination is highly specific for fluid, the sensitivity is poor ranging from 46% to 67%.²⁵⁻²⁷ In the hemodynamically *unstable* patient with multiple cavitory sources of hypotension, a positive FAST can still be helpful as a rapid tool for operative incision planning. For *stable* patients however, it rarely impacts clinical decision-making as the patient either meets criteria for selective non-operative management and will be undergoing CT, or will be going to the OR, irrespective of the FAST findings.

CT has become universally accepted as an integral component in the evaluation of the penetrating trauma patient undergoing selective non-operative management. For patients undergoing exploration, CT is unnecessary and should not be routinely obtained. For patients with a GSW who are stable, evaluable, and without peritonitis and are undergoing a trial of non-operative management however, CT is a requisite next step.

GSWs follow a linear path and have an associated air bubble tract that allows for trajectory identification on CT scan. Understanding the missile trajectory provides critical information regarding potentially injured structures and those to which injury is unlikely. CT scan imaging after abdominal GSWs has been shown to be highly reliable for injury identification, with a sensitivity and specificity of 90.5% to 96% and 95% to 96%, respectively.^{28,29} The injury tract on CT scan is often more subtle after SWs due to the lower velocity and smaller volume of air bubbles along the tract, and as a result, CT scan has been shown to be a less useful³⁰ adjunct in patient triage.^{30,31}

Based on the CT scan findings, patients may be divided into four groups. (1) Patients with no peritoneal violation on CT scan. In this population, it is exceedingly rare that operative intervention will be required. (2) Patients with peritoneal violation but no obvious intra-abdominal injury on CT scan. This is the ideal patient population for selective non-operative management with serial abdominal examinations and observation. (3) Patients with peritoneal violation and evidence of vascular or hollow viscus injury on CT scan. Although there are no strict criteria for diagnosing hollow viscus injury on CT scan, findings concerning for injury include bowel wall edema, missile trajectory traversing bowel, extraluminal fluid, air, or contrast. In this group, laparotomy is mandatory. (4) Patients with peritoneal violation and solid organ injury. In the absence of hollow viscus injury, solid organ injury alone does not mandate laparotomy.^{32,33} For patients meeting all other criteria for non-operative management, this remains a treatment option with a high rate of success.

For patients with a GSW and an equivocal finding on CT or for patients with a SW undergoing non-operative management, clinical observation becomes the next important step. This is the most time-consuming aspect of non-operative management and one of the primary reasons it is not feasible in all practice settings. This observation should be performed by a consistent team, ideally by the same provider, who can carefully examine for changes in abdominal pain, collateral markers of occult injury such as tachycardia or fever, and laboratory abnormalities such as an increasing white blood cell count. During this observation period, it is expected that a certain percentage of patients initially selected for non-operative management will progress to operative intervention based on imaging or changes in clinical examination. Selective non-operative management hinges on the ability to perform frequent, consistent physical examinations. Patients should receive no narcotics, anesthetics, or antibiotics and undergo serial hemodynamic and laboratory testing including white blood cell count, lactate, and hemoglobin levels. Strict adherence to a protocol is necessary to ensure early identification of patients who fail non-operative management and require operative intervention.

In patients selected for non-operative management after penetrating abdominal wounds, the duration of observation is individualized based upon the clinical scenario. After abdominal GSWs, a review of 270 patients found that all injuries requiring laparotomy were apparent within 24 hours of observation.^{34,35} Similar results have been described for abdominal SWs with injuries requiring laparotomy detected within 12 hours of observation.³⁶

Penetrating left thoracoabdominal injuries, bounded by the nipple, scapular tip, and costal margin, present a unique challenge due to the risk of occult diaphragmatic injury. Diaphragmatic injuries are notoriously difficult to diagnose on CT scan and are often asymptomatic in the early, postinjury setting. Over time, as the injury expands, the patient will be at risk for visceral herniation and strangulation. This complication is less likely after right-sided injuries due to buttressing of the injury by the liver but is a serious consideration after left-sided injury. The incidence of diaphragmatic injury after thoracoabdominal injury is as high as 17% to 40%.³⁷⁻³⁹ For this reason, patients treated non-operatively for left thoracoabdominal penetrating injuries should undergo a period of clinical observation. If peritonitis develops, the diaphragm can be directly examined at laparotomy. If the patient passes the period of observation, the patient can be offered diagnostic laparoscopy to specifically evaluate the diaphragm on the left side. As the patient has already been clinically evaluated and other intra-abdominal injury excluded, laparoscopy can be focused on diaphragmatic evaluation and a full exploration is not necessary. Insufflation for this procedure should be done carefully with close monitoring of the vital signs. With any evidence of the development of tension physiology due to a diaphragmatic injury, immediate release of pressure and insertion of a chest tube should be performed before proceeding.

THE TRAUMA LAPAROTOMY

3 For any hospital that cares for trauma patients, the ability to emergently perform an operative intervention is critical. Preparation before the critically ill patient arrives is key. An operating room that is easily accessible from the resuscitation area as well as the ICU should be earmarked for use in these situations. A plan for securing the room for high-profile patients should be in place and there should be a designated waiting area for family members. A contingency plan for multiple casualty situations should be available, with operating rooms located in close proximity to facilitate surgical, anesthesia, and nursing cross-coverage. Transportation of critically ill patients is a high-risk situation, and preplanned routes that minimize distance, elevator use, and public exposure should be well known to all providers. Instruments and disposables should be centrally located and redundant so that multiple casualty situations can be dealt with effectively. Having a dedicated trauma pack that allows for a laparotomy and thoracotomy, with add on sets for a sternotomy, amputation, and peripheral vascular injuries will facilitate circulator efficiency. With the high rate of retained foreign bodies after emergent trauma cases, the use of radiofrequency detection device embedded fabric is recommended. In higher-volume centers, access to a satellite blood bank with uncross-matched packed red blood cells and plasma is ideal, otherwise a system for communication with the main blood bank and product delivery to the OR should be developed and practiced. If a hybrid room is available, the operative team and nursing team should be familiar with the indications for starting an emergent case in this room. For all rooms, access to fluoroscopy and plain films is critical. Because of service line cross-coverage, ongoing inservicing of the nursing and support staff is important to ensure that practices such as massive transfusion protocols, are universally understood.

4 For all emergent laparotomies, the patient should be placed in the supine position with arms abducted at 90 degrees. Even with a concomitant thoracic injury, this is the preferred starting position. Rarely, for patients with a penetrating injury with a transpelvic trajectory, where endoscopic evaluation may be required, the lithotomy position may be used. Likewise, in the blunt trauma patient where there is external perineal injury, this may be considered. At a minimum, the torso, neck, and upper half of the lower extremities should be prepared into the field for maximum flexibility. With any concurrent limb injuries, the entire extremity should be prepared. If there is any concern of a urethral or bladder injury, the Foley catheter should be prepared into the field to allow manipulation by the surgeon. Forced air warming on the lower half of the extremities, and other warming adjuncts should be utilized. All preoperative patient preparation including venous and arterial access, catheterization, and confirmation of patient identification should be a team effort with full participation by the surgical team.

The trauma laparotomy incision extends from the xiphoid process to the symphysis pubis.

Traditionally made with a scalpel, unless emergent, electrocautery can be utilized to minimize bleeding. This extensile midline incision can be extended across the right or left inguinal ligament for distal iliac vascular injuries. Superiorly, a subcostal extension can be added to improve access to the liver on the right, especially with retrohepatic venous injuries, or to the left for gastroesophageal (GE) junction injuries. The incision can be extended into a sternotomy for concurrent thoracic cavity injuries or to facilitate suprahepatic vena cava control for high-grade liver injuries not amenable to packing. If the patient has a pre-existing right thoracotomy, this can be joined to the laparotomy with incision of the diaphragm to afford the same view of the liver, retrohepatic venous structures, and intrapericardial vena cava.

On entry to the abdomen, the falciform should be taken down so as to minimize traction damage to the liver. Traditionally, blind four quadrant packing was advocated. In reality, this maneuver is not very helpful. In order to prevent iatrogenic damage, it is preferable to remove large amounts of central clotted blood, followed by selected packing of any areas with active bleeding. A rapid examination of the retroperitoneum should also be performed. Focusing on an obvious bowel injury that is encountered first while a retroperitoneal vascular injury remains unattended to is a pitfall. The goal of the initial packing and survey of contents is to identify and temporize any major sources of bleeding. A plan for surgical control can then be made. This includes notifying the circulator of any necessary additional equipment and close communication with anesthesia to optimize the resuscitation needs of the patient. Early consideration of damage control, addressed later in the chapter should be considered. The need for adjunctive services such as angiography prior to proceeding to the SICU should be considered and initiated early to allow lead-time for preparation. Once active hemorrhage has been temporized, a careful and complete survey of all of the abdominal contents should be performed. In the exsanguinating patient who is undergoing a damage control procedure, this may not be possible, but in the stable patient, this is critical. The potential for a missed injury can be mitigated by a systematic approach to the abdominal contents. We recommend that the entire abdomen be reviewed in the same manner for every case, regardless of the mechanism. For example, even a patient with a clear transpelvic GSW trajectory should have their upper abdomen inspected because a fragment undetected on the preoperative imaging may have caused an unexpected colon injury or, a concurrent blunt splenic injury may have been sustained by the patient and not elicited on the initial history. Specific areas warrant extra care during the examination. For blunt injuries without preoperative imaging, duodenal injuries may present with only a subtle hematoma in the retroperitoneum. For hematomas in this area, a right visceral medial rotation should be performed. For penetrating injuries, especially those due to shotguns, colonic, rectal, and small bowel injuries, especially on the mesenteric surface may only be visible as a small bloodstain or hematoma in the overlying fat. These need to be inspected carefully. The posterior surface of the stomach is also a common area for missed injuries and should be inspected carefully.

While exceedingly uncommon for blunt injuries, for both SWs and GSWs, ureteric injuries can be difficult to diagnose and for any trajectories in this region, care should be taken to inspect the at-risk segment of the ureter without devascularizing the structure. Likewise, whereas blunt bladder injuries are often large and located near the dome, penetrating injuries, even those that are intraperitoneal, can be small and asymptomatic. Most small extraperitoneal injuries can be managed non-operatively with urinary catheter drainage however, large injuries, especially those with an intact connection to the skin can be problematic. If there is an intraperitoneal component of bladder injury, this can be extended and the interior of the bladder visualized. If not, we recommend injection of methylene blue containing sterile water into the bladder retrograde to look for any gross extravasation. If this is identified, the bladder should be taken down and these injuries repaired.

For retroperitoneal hematomas, the abdomen is traditionally broken down into three zones. Zone I is the central portion from the aortic hiatus to the sacral promontory encompassing the aorta, IVC, and major branches. Zone II covers the lateral retroperitoneum which contains the kidneys. Zone III is the pelvis, which encompasses the sacral venous plexus and iliac vessels. For penetrating injuries, all zones undergo exploration. For blunt injuries, traditionally, all zone I hematomas would be explored with zones II and III only warranting exploration if the hematoma was large, expanding or pulsatile. The retrohepatic area is distinct from the remaining areas and we often refer to this as zone IV, containing the retrohepatic IVC and major hepatic veins. This area is difficult to expose and control and as such, if controllable with packing, should not be explored for either blunt or penetrating injuries.

DAMAGE CONTROL LAPAROTOMY

5 Damage control⁴⁰ has become a common practice in the management of patients with complex abdominal trauma and has been credited with saving more lives than many of the other surgical techniques developed over the last two decades. Abdominal damage control techniques should always be combined with damage control resuscitation, which includes permissive hypotension, early empiric balanced blood component therapy minimizing crystalloid usage, and the prevention and treatment of hypothermia. Abdominal damage control includes three key components: (a) temporary rapid control of bleeding and contamination with early termination of the operation, (b) postoperative resuscitation with correction of coagulopathy, hypothermia, and acidosis, and (c) subsequent definitive repair of injuries.

The standard indications for damage control include: (a) patients with severe physiologic compromise with coagulopathy, hypothermia, or acidosis, (b) bleeding from difficult to control injuries or an injury burden which will result in physiologic compromise if treated definitively at the index operation, and (c) austere environments with limited resources or surgeon skillset, such as in a rural or combat setting. There is evidence that early damage control, even prior to physiologic decompensation, may be associated with better survival and as such, patients with a large injury burden at risk of becoming physiologically depleted should also be considered as candidates for damage control surgery. The exact timing of damage control should be determined by the complexity of the injuries, the physiologic condition of the patient, the available resources, and the experience of the surgical team.

Effective temporary hemorrhage control can be achieved by mechanical compression or gauze packing in most cases where there is bleeding from surfaces such as complex liver injuries, the retroperitoneum, or the pelvis. However, packing is usually not effective for major vascular injuries and surgical control with ligation or shunting⁴¹ may be necessary. For deep tracts, for example in the liver, balloon tamponade⁴² can be very effective (Fig. 25-2). Angioembolization may be a useful adjunct for abdominal damage control and should be considered early, immediately following the operation. A hybrid operating room may be a valuable tool, facilitating simultaneous operation in the abdomen and angioembolization of difficult bleeding sites.

Figure 25-2. Gunshot injury through the center of liver requiring balloon tamponade using Foley catheters for damage control.

Control of intestinal spillage is also an integral part of abdominal damage control. It has been suggested that ligation or stapling of the injured bowel, without reestablishing continuity, should be considered as part of damage control for intestinal injuries requiring resection. Definitive reconstruction is performed at a later stage, once the patient is stabilized, often 24 to 36 hours after the initial operation. There are concerns that this approach may create a complete intestinal obstruction, which may promote bacterial and toxin translocations or aggravate bowel ischemia, especially in patients requiring vasopressors. Although not always possible, reconstruction of the bowel or creation of an ostomy for diversion should be considered at the index operation if tolerated by the patient.

Damage control should be performed in an organized and orderly fashion, making sure that no significant injuries are missed and that there is effective control of hemorrhage and contamination. The procedure should not be terminated if there is persistent bleeding.

6 Following damage control, the abdominal fascia or skin should never be closed because of the high risk of intra-abdominal hypertension and abdominal compartment syndrome.⁴³ The abdomen should be temporarily closed. The ideal method of temporary abdominal closure should prevent evisceration, preserve the fascia and abdominal wall domain, facilitate reoperation, allow effective removal of toxin-loaded intraperitoneal fluid, reduce the risk of enteroatmospheric fistulas, and help achieve early

definitive fascia closure ([Fig. 25-3](#)).

Numerous materials and techniques have been used for temporary abdominal closure over the last decade. A widely used technique in the past was passive closure with simple materials, such as a sterile x-ray cassette cover, which is stapled or sutured to the fascia or the skin. This method does not allow effective removal of any contaminated or toxin and cytokine-rich intraperitoneal fluid, and does not prevent the loss of abdominal wall domain. Most contemporary systems now include the addition of negative pressure. This can be made using perforated plastic sheeting, adhesive drapes, drains and laparotomy packs, or a commercially available device. There is evidence that these negative pressure dressings may improve survival and increase the success rate of primary fascia closure.

Once the patient has had their initial abbreviated procedure and temporary abdominal wall closure, they can then be taken to the ICU for continuation of the resuscitation which was started in the OR. After physiologic status has normalized, the patient can then return to the OR for definitive exploration and repair of all injuries. Even prior to normalization of the patient's physiology, if significant bleeding is noted in the negative pressure system, the pressure should be immediately discontinued and the patient returned to the operating room for reexploration and bleeding control. Although rare, even with a temporary abdominal wall closure in place, intra-abdominal hypertension may still occur. It is important that bladder pressures are monitored routinely during the first few hours after laparotomy, even if it was a damage control procedure with the abdomen left open.

Figure 25-3. Temporary abdominal closure after damage control laparotomy.

DIAPHRAGM

Anatomy

The diaphragm consists of a central aponeurotic portion which fuses with the pericardium and a peripheral muscular portion which is attached to the lower sternum, the lower six ribs, and the lumbar spine. During exhalation, the diaphragm rises to the level of the nipples at the fourth to fifth intercostal space. Penetrating injuries of the lower chest or insertion of a thoracostomy tube below the nipple, therefore has the potential to cause injury to the diaphragm.

Epidemiology

In a prospective study of 119 consecutive patients with penetrating injuries to the left thoracoabdominal region (nipple and tip of the scapula superiorly, costal margin inferiorly), undergoing laparotomy or laparoscopy,³⁸ a diaphragmatic injury was identified in 59% of GSWs and 32% of SWs. There were no differences between anterior, lateral, or posterior injuries. Blunt trauma may cause diaphragmatic injury through three different mechanisms which include a sudden increase in intra-abdominal pressure causing a bursting of the diaphragm, fractured ribs perforating the diaphragm, and deceleration injuries causing detachment of the diaphragm from the ribs. For blunt trauma, a diaphragmatic injury is found in approximately 7% of all laparotomies and in about 7.5% of autopsy studies. The left hemidiaphragm is involved in approximately 70% of cases and the right in 30% presumably due to the protective presence of the liver. Blunt tears ([Fig. 25-4](#)) are usually 7- to 10-cm long as compared with 2 to 3 cm for penetrating trauma ([Fig. 25-5](#)). A right diaphragmatic rupture indicates a more severe traumatic insult and in almost all cases there are associated intra-abdominal injuries, compared to 77% for left diaphragmatic ruptures.

Figure 25-4. Large blunt diaphragm injury.

Figure 25-5. Small diaphragm injury after a stab wound to the left thoracoabdominal region.

Diagnostics

Isolated and uncomplicated diaphragmatic injuries are difficult to diagnose as they may be completely asymptomatic or present with minor, nonspecific abdominal signs. The classic signs and symptoms normally associated with diaphragmatic injury such as shortness of breath, bowel sounds in the chest, GI obstruction, or ischemia, are relatively rare, and require acute herniation of abdominal contents.

The natural history of unrecognized diaphragmatic injuries is unknown and although some small injuries may heal, this is not uniform. For right hemidiaphragm injuries, the presence of the liver generally protects against diaphragmatic herniation. However, for the left side, unrepaired diaphragm injuries commonly result in a diaphragmatic hernia, which may present within hours, days, weeks, months, or even years after the injury.

Due to the occult presentation and the risks of unrecognized diaphragmatic injuries, for penetrating trauma, all patients with a wound to the left thoracoabdominal area, defined as the area between the nipple and scapula superiorly and the costal margin inferiorly, should be aggressively evaluated for diaphragm injury. Plain chest x-ray and CT are unreliable in detecting uncomplicated diaphragm injuries as the injuries are often very small. For patients undergoing laparotomy, care should be taken to inspect the diaphragm. If the patient is to be managed non-operatively, as mentioned earlier in the chapter, delayed laparoscopic evaluation is warranted.

For larger blunt injuries, imaging can be more useful. Plain radiologic findings suspicious of diaphragmatic injury include an elevated diaphragm, an irregular diaphragmatic contour, and nonvisualization of the diaphragm. Classically, an NG tube may be seen in the thoracic cavity. Once GI tract herniation has occurred, chest x-ray (Fig. 25-6) and CT (Fig. 25-7) have higher sensitivity. CT scan is the highest-yield investigation because it also includes any associated intra-abdominal injuries and has a higher sensitivity than plain radiographs, especially for newer multidetector CT scans.⁴⁴

Treatment

For patients where there is suspicion of a diaphragmatic injury with herniation, care should be taken to avoid perforation of any hollow viscus in the chest. All diaphragm injuries should ultimately have the abdominal contents reduced and the defects repaired. Acutely, diaphragmatic injuries should be

approached through a laparotomy to facilitate exploration of the remaining intra-abdominal contents. In chronic, elective cases, access and repair of the hernia can be performed through a thoracotomy. The repair should be performed using nonabsorbable sutures and if there is contamination of the pleural cavity, extending the incision and washing the cavity out prior to closure are warranted. Tube thoracostomy should be considered in most cases. In rare cases where there is loss of diaphragmatic tissue, synthetic prosthetic reconstruction can be utilized. If the diaphragm has been avulsed from the chest wall, careful reconstruction of the diaphragmatic architecture utilizing nonabsorbable sutures is required. In some cases where there is significant tissue loss, apposition of the remaining diaphragm to the chest wall several rib spaces up may be required to create a tension-free repair.

Figure 25-7. CT demonstrating left blunt diaphragmatic injury with herniating gastrointestinal tract contents.

LIVER AND BILIARY TRACT

Anatomy

The anatomical division of the liver into the eight classic Couinaud segments has no practical application in trauma. Parenchymal resection should be minimized and does not follow any anatomical boundaries. An understanding of the blood supply however is important. The retrohepatic IVC is approximately 8- to 10-cm long and in most patients is partially covered by the liver parenchyma. In approximately 7% of individuals the IVC is completely embedded in the liver. For outflow, there are three major hepatic veins (right, middle, and left), with numerous accessory veins. Only the proximal 1 to 2 cm of the major hepatic veins are extrahepatic. In approximately 70% of individuals, the middle hepatic vein joins the left hepatic vein, near the IVC. The portal vein provides approximately 70% of hepatic blood flow, and 50% of the hepatic oxygenation. It divides into right and left branches at the level of the liver parenchyma. The common hepatic artery originates from the celiac artery. In most individuals it

branches into the left and right hepatic arteries at the hilum of the liver. In some individuals the right hepatic artery originates from the superior mesenteric artery. The left hepatic artery may originate from the left gastric artery. The porta hepatis contains the hepatic artery to the left, and the common bile duct to the right. The portal vein lies posteriorly and between the common bile duct and the hepatic artery. The left hepatic bile duct, the left hepatic artery, and the left portal vein enter the undersurface of the liver, near the falciform ligament.

Epidemiology

The liver is one of the most commonly injured intra-abdominal organs following blunt trauma. The mechanisms of injury include direct blunt force compression, penetration by a fractured rib, and deceleration with avulsion of the ligaments or the hepatic veins. In penetrating trauma the liver is the most commonly injured solid organ. Low-velocity missiles cause limited tissue damage and are life-threatening only if they cause injury to a major vessel. High-velocity missiles can cause massive tissue destruction and are associated with high mortality. The AAST-OIS grading system (Table 25-1) ranges from a mild grade I injury to a grade VI total hepatic avulsion which is lethal.⁴⁵

Table 25-1 OIS-AAST Grading Scale for the Liver

Grade ^a	Type	Injury Description
I	Hematoma Laceration	Subcapsular, <10% surface area Capsular tear, <1 cm parenchymal depth
II	Hematoma Laceration	Subcapsular, 10–50% surface area; intraparenchymal, <10 cm in diameter 1–3 cm parenchymal depth, <10 cm in length
III	Hematoma Laceration	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma, >10 cm or expanding >3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25–75% of hepatic lobe or 1–3 Couinaud segments within a single lobe
V	Laceration Vascular	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe Juxtahepatic venous injuries; that is, retrohepatic vena cava/ central major hepatic veins
VI	Vascular	Hepatic avulsion

^aAdvance one grade for multiple injuries, up to grade III.

Diagnostics

A FAST will detect free intraperitoneal bleeding, but it does not provide any information about the source of this bleeding. A formal ultrasound performed by an experienced radiologist may provide additional information regarding the grade of the hepatic injury but this is not practical for acutely injured patients. An abdominal CT scan with intravenous contrast is the most widely used and highest-yield modality. CT provides accurate information about the architecture of the injury, the amount of intraperitoneal blood, the presence of active bleeding, pseudoaneurysms or arteriovenous fistulas, and the presence of associated injuries. CT is a valuable tool in the selection of patients for operation, angiographic embolization, or observation (Fig. 25-9).

Treatment

Selective non-operative management of blunt liver trauma is the only acceptable contemporary standard of care. The selection of patients for non-operative management should incorporate clinical examination, CT scan findings, and the presence or absence of associated injuries. Hemodynamic stability and the absence of peritonitis are absolute requirements for non-operative management. The success rate of non-operative management for blunt hepatic trauma, including those with high-grade injuries, is high.^{46,47} In a recent National Trauma Data Bank study of 6,402 patients with grade IV or V blunt liver injuries, 68% were managed non-operatively.⁴⁸ For these high-grade injuries, especially with evidence of contrast extravasation (Fig. 25-8), angiointervention has been shown to be an independent predictor of survival and should be used liberally as a postoperative adjunct. Most failures of non-operative management occur within the first 24 hours of admission. There is some evidence that patients with high injury severity score (ISS), severe grade IV or V liver injuries, multiple transfusions,

major associated injuries, and associated chronic conditions such as cirrhosis, are at an increased risk for failure of non-operative management. Angiographic embolization may be a significant adjunctive therapeutic modality which increases the success rate of non-operative management of high-grade injuries.^{47,49} Although non-operative management of blunt liver trauma has become the standard of care, many centers still treat penetrating injuries operatively. However, there is good evidence that at experienced trauma centers, selected cases with penetrating trauma due to SWs or GSWs (Fig. 25-9), can safely be managed non-operatively.^{32,33} For both blunt and penetrating injuries being managed non-operatively, continuous close monitoring in an ICU environment and frequent serial clinical examinations are critical for success.

Figure 25-8. High-grade blunt liver injury with active contrast extravasation.

For operative management, the initial incision should be a midline laparotomy because it provides adequate exposure of the liver in the majority of cases and allows systematic exploration of the abdomen. For improved access to posterolateral liver injuries, a right subcostal incision may be required. In rare occasions, addition of a sternotomy may be required in order to obtain access to the intrapericardial inferior vena cava for total vascular isolation of the liver (Fig. 25-10), or exposure of the heart for placement of an atriocaval shunt (Fig. 25-11). Alternatively, as discussed earlier in the chapter, if the patient has a right thoracotomy, usually in the setting of a gunshot injury which presented with a massive hemothorax due to decompression of a high-grade liver injury through the diaphragm, the thoracotomy and laparotomy can be joined with incision of the diaphragm for unimpeded access to the posterior liver and suprahepatic segment of the IVC.

In this case a cuff of diaphragm should be left so that if the patient survives, reconstruction is facilitated. In approximately 80% to 85% of patients undergoing operation, the liver injury can be managed by relatively simple surgical techniques, such as application of local hemostatic agents, electrocoagulation, or superficial suturing. Bleeding from deep liver lacerations can be controlled by clipping or suture ligation of any major vessels, followed by deep, figure-of-eight sutures, on a large blunt liver needle. Omental packing of large liver defects is useful in eliminating any dead space. Significant bleeding from deep bullet or knife tracts in the liver may require a tractotomy for peripheral wounds or balloon catheter tamponade and perihepatic packing for central wounds.

Figure 25-9. Gunshot injury to the liver successfully managed non-operatively.

Figure 25-10. Laparotomy and sternotomy demonstrating excellent access to the liver and the intrapericardial segment of the suprahepatic IVC.

7 Severe blunt trauma or high-velocity GSWs associated with extensive parenchymal damage are not amenable to deep suturing. Bleeding control in these cases may be achieved with perihepatic packing, with or without liver resection. Perihepatic packing and damage control is a significant advancement in the management of complex liver injuries. In order to be effective it needs to be performed early, before the patient becomes unstable. The presence of intact hepatic ligaments enhances the effectiveness of the perihepatic packing and they should not routinely be divided. Laying a piece of absorbable mesh on the raw surface of the liver prior to packing facilitates pack removal at the take back as the mesh with its integrated clot can be left undisturbed once the packs are removed. Angioembolization following perihepatic packing should be considered early postoperatively and ideally, intraoperatively, if a hybrid operating room (Fig. 25-12) is available. The perihepatic packing should be removed after correction of coagulopathy and other physiologic abnormalities, usually within 24 to 36 hours of the index operation. Delaying the removal of the packs for more than 48 hours may be associated with an increased risk of infection. Nonanatomic liver resection may be needed in cases where there is a destructive injury, and perihepatic packing is not effective.⁵⁰ In general however, packing is highly effective and major anatomic hepatic resections are rarely indicated acutely. Once the patient has stabilized, and the liver has demarcated and the patient is able to tolerate resection, any nonviable parenchyma can be resected. If required acutely, the liver resection can be performed with finger dissection of the parenchyma, with suture ligation of vessels and biliary branches, or with the use of an electrothermal bipolar vessel sealing system. Selective hepatic artery ligation or clipping may be a useful adjunct to packing in rare cases and should be considered if packing by itself is insufficient and temporary occlusion results in reduction of the bleeding. The combination of hepatic artery occlusion, extensive parenchymal injury, and hypotension increases the risk of hepatic necrosis.

Figure 25-11. Schematic demonstrating an atriocaval shunt. (From Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. New York, NY: Cambridge University Press; 2015, with permission.)

Figure 25-12. Hybrid operating room.

In the rare situation where perihepatic packing is not effective, often due to major retrohepatic venous injuries, total vascular isolation of the liver may be required to achieve temporary bleeding control, allowing identification and ligation of the injured vessels. The procedure consists of cross-clamping of the infradiaphragmatic aorta, the suprahepatic and infrahepatic inferior vena cava, and the porta hepatis. Control of the suprahepatic IVC is extremely challenging in the intra-abdominal segment as this is usually where the primary source of bleeding necessitating the procedure has occurred. Consequently, it is recommended that the intrapericardial segment as described earlier is accessed for control.

Injury to the retrohepatic venous structures should be suspected in the presence of retrohepatic bleeding or hematoma, especially if the bleeding becomes worse when the liver is retracted anteriorly. Characteristically, the bleeding is reduced with posterior compression of the liver. A noncontained retrohepatic venous injury is highly lethal because of the difficult surgical exposure. As discussed earlier, contained retrohepatic hematomas should not be explored because of the risk of uncontrollable hemorrhage. This applies to both blunt and penetrating injuries. However, in the presence of active bleeding not controlled by packing and posterior compression of the liver, exploration and repair or ligation of the bleeding vessel are mandatory. Addition of a subcostal incision improves exposure of the liver and the retrohepatic veins. Division of the falciform and coronary ligaments allows inferior-medial rotation of the liver and direct visualization of the inferior vena cava and the right hepatic vein. As described earlier, an alternative to the subcostal incision is a median sternotomy or if the patient already has a right anterolateral thoracotomy, division of the diaphragm, straight down to the inferior vena cava.

The use of an intracaval shunt may be considered in selected complex retrohepatic venous injuries which cannot be controlled with simpler approaches. The procedure involves extension of the laparotomy incision into a median sternotomy and opening of the pericardium. A tape tourniquet is then applied around the intrapericardial IVC. A purse-string suture (2-0 silk) is placed in the right atrial appendage and a size 8 endotracheal tube with a side hole cut at approximately 8 to 10 cm from the clamped proximal end, is then inserted through the purse-string and guided into the IVC. The balloon of the tube is then inflated just above the renal veins and the tape tourniquet around the intrapericardial IVC is tightened.⁵¹ Alternatively, a 36-Fr chest tube, with fenestrations cut into the proximal segment of the tube to allow blood flow from the IVC into the right atrium may be used. The intracaval shunt may reduce bleeding but in reality, rarely achieves complete hemostasis. The reported results with atriocaval shunts are generally poor, and should be considered if all other techniques have failed.

For completion, other techniques which have been used in the management of retrohepatic venous injuries include intravascular balloons inserted through the femoral vein, extracorporeal venovenous bypass, hypothermic circulatory arrest, and liver transplantation.⁵²

The incidence of postoperative liver-related complications after high-grade liver injuries has been reported to be as high as 50%.⁵³ The clinical presentation of these complications may vary from a few days to many months. Complications include early or late hemorrhage, pseudoaneurysm, arteriovenous fistula, biloma, biliary fistula, liver necrosis, liver abscess, hemobilia, and intrahepatic biliary strictures. Approximately 35% of patients with significant liver-related postoperative complications are asymptomatic and have the complication diagnosed on CT.⁵³ The majority of these complications can safely be managed non-operatively, with percutaneous endovascular or endoluminal interventional radiology-based or ERCP-guided solutions.

Extrahepatic Biliary Tract Injury

Trauma to the extrahepatic biliary tree is rare and is usually due to a penetrating mechanism. Bile duct injuries are usually diagnosed during laparotomy, although some cases may present late, occurring even days after injury. The diagnosis may be confirmed with a hepatobiliary iminodiacetic acid (HIDA) scan, MRCP, or ERCP. The management of injuries to the biliary tree is determined by the location and extent of the biliary injury, the time of diagnosis, and the presence of associated intra-abdominal injuries. Injuries to the gallbladder are treated by cholecystectomy. Complete duct transections are best managed with a Roux-en-Y biliary-enteric anastomosis because primary repair is associated with a high stricture rate.

Incomplete injuries to the extrahepatic ductal system discovered intraoperatively, can be managed with primary repair, if the transection involves less than 50% of the duct circumference. Placement of a T-tube through a separate choledochotomy facilitates the repair. Transections involving more than 50% of the circumference of the duct, especially with questionable tissue viability, should be treated like a complete transection. All repairs of the biliary tract should be drained externally with closed suction drains.

In the damage control setting, the duct may be ligated or an external catheter may be placed into the proximal duct and exteriorized through the skin. Definitive repair can be performed after physiologic stabilization of the patient or once expert assistance becomes available.

SPLEEN

Anatomy

The spleen is held in place by four ligaments which include the splenogastric ligament medially, the splenocolic ligament inferiorly, and the splenophrenic and splenorenal ligaments posterolaterally. The splenogastric ligament is the only vascular ligament and contains five to seven short gastric vessels, which originate from the distal splenic artery. The tail of the pancreas is in close proximity to the splenic hilum and is at risk of injury during splenectomy or hilar clamping. The splenic artery courses superior to the pancreas and near the splenic hilum it divides into upper and lower pole arteries. The splenic vein is located posterior and inferior to the splenic artery, receives the inferior mesenteric vein and joins the superior mesenteric vein to form the portal vein.

Epidemiology

The spleen is a commonly injured intra-abdominal organ following blunt trauma and the second most commonly injured solid organ after penetrating trauma. The severity of splenic injury is graded by the OIS-AAST spleen injury scale, which is based on CT, as well as operative findings ([Table 25-2](#)). Generally, grades I and II are considered minor injuries, grade III a moderate injury, and grades IV and V are severe injuries.

Diagnostics

The clinical presentation of a spleen injury depends on the volume of blood loss and the presence of associated injuries. Many low-grade splenic injuries may be asymptomatic or have only minor local tenderness and the diagnosis is made on CT. If associated with significant blood loss the patient may present with tachycardia and hypotension. Classically, those with large splenic hematomas may experience pain in the left upper quadrant, radiating to the left shoulder (Kehr sign), especially when placed in the Trendelenburg position. Although plain chest x-rays are not diagnostic, the presence of fractures of the left lower ribs or an elevated left hemidiaphragm can be associated with an increased possibility of splenic injury. The FAST may show free fluid around the spleen. Abdominal CT scan with intravenous contrast is the most widely used and highest-yield investigation ([Figs. 25-13](#) and [25-14](#)). It provides accurate information about the grade of injury, the amount of intraperitoneal bleeding, evidence of active bleeding, and associated injuries.

Table 25-2 OIS-AAST Grading Scale for the Spleen

Grade ^a	Type	Injury Description
I	Hematoma Laceration	Subcapsular, <10% surface area Capsular tear, <1 cm parenchymal depth
II	Hematoma Laceration	Subcapsular, 10–50% surface area, <5 cm in diameter 1–3 cm parenchymal depth not involving a trabecular vessel
III	Hematoma Laceration	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma, ≥5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of the spleen)
V	Laceration Vascular	Shattered spleen Hilar vascular injury with devascularized spleen

^aAdvance one grade for multiple injuries, up to grade III.

Figure 25-13. CT image of a high-grade spleen injury.

Treatment

Approximately 80% of blunt splenic injuries in adults and 90% to 95% in children can be safely managed non-operatively.⁵⁴ Recent studies suggest that approximately 10% of all penetrating splenic injuries may also be managed non-operatively.⁵⁵ The selection of patients for non-operative management should be based on clinical examination and CT scan findings. The patient should be hemodynamically stable and have no signs of peritonitis. Although associated head trauma is not an absolute contraindication for non-operative management, it should lower the threshold for operative intervention, because head trauma-related coagulopathy increases the risk of splenic bleeding and the splenic bleeding may cause hypotension which would be detrimental to the injured brain.

Figure 25-14. Spleen after removal as seen on CT in [Figure 25-13](#).

Low-grade splenic injuries are much more likely to be successfully managed non-operatively, but many high-grade injuries may still be managed non-operatively. Patients with higher-grade splenic injuries selected for non-operative management should be observed in the ICU. Development of hemodynamic instability, peritonitis or the need for blood transfusion should trigger operative exploration. Most failures occur within the first few days, although in some cases, especially those with subcapsular hematomas or pseudoaneurysms, delayed bleeding may occur days to weeks after the injury. Patients with severe splenic injuries selected for non-operative management should receive prophylactic vaccinations against *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*, in case conservative management fails and the patient requires splenectomy.

A follow-up CT scan should be performed for all grade III to V splenic injuries within 2 to 3 days of admission to rule out the development of a pseudoaneurysm or progression of the hematoma. Subsequent follow-up CT scan evaluation should be considered in selected cases with high-grade injuries, especially those with subcapsular hematomas.

The duration of avoidance of vigorous physical activities and contact sports should be individualized, taking into account the severity of the spleen injury, the findings on follow-up CT scan, and patient's lifestyle. Most surgeons recommend a period of approximately 4 to 6 weeks before resumption of heavy duties.

Angioembolization has been used as an adjunct to non-operative management in high-grade splenic injuries. For patients with CT scan evidence of active contrast extravasation or pseudoaneurysm, angioembolization should be considered. Proximal splenic artery embolization consists of coil occlusion of the splenic artery distal to the dorsal pancreatic artery and promotes hemostasis by reducing blood flow to the spleen. Distal selective embolization consists of coil or gelfoam deployment as close to the bleeding site as possible. The available evidence is inconclusive and suggests that the two approaches may be equally effective in preventing significant rebleeding. Both techniques are associated with the same incidence of infarctions and infections requiring splenectomy. Distal embolization is associated with a higher rate of asymptomatic segmental infarctions.⁵⁶ A Western Trauma Association multicenter trial which included 140 splenic artery embolizations reported an overall complication rate of 32%, including splenic infarctions in 21% and splenic abscess in 4.3%.⁵⁷

For operative management, midline laparotomy is the incision of choice for accessing the spleen. After entering the peritoneal cavity any free blood is evacuated and the left upper quadrant is packed for temporary bleeding control. This allows a rapid evaluation of the rest of the abdomen to rule out any other major injuries which may require immediate attention. The next step is the assessment of the type and severity of the splenic injury, in order to determine if the spleen is salvageable. After removal of the temporary packing, the organ is rotated inferomedially. Several laparotomy pads are then placed under the left diaphragm and behind the spleen, aiding in the exposure of the spleen. Excessive traction on the stomach or the splenic flexure of the colon or excessive medial rotation of the spleen may cause avulsion of the delicate splenic capsule, resulting in bleeding and decreasing the possibility of splenic preservation.

Profuse bleeding from the spleen can temporarily be controlled with digital compression of the hilum or direct digital compression of the splenic parenchyma. A vascular clamp can also be placed across the hilum, taking care not to injure the tail of the pancreas.

The critical move for a quick and safe splenectomy is adequate mobilization and inferomedial rotation of the spleen. This is achieved by sharp division of the splenophrenic and splenorenal ligaments posterolaterally and medial rotation of the spleen. The next step is division and ligation of the vascular gastrosplenic ligament, as far away from the stomach as possible, in order to avoid injury or ischemic necrosis of the gastric wall. Likewise, the splenic artery and vein should be ligated as close to the hilum as possible, in order to avoid injury to the tail of the pancreas. The final step is division of the splenocolic ligament. Although this stepped approach to mobilization of the spleen is applicable to most patients, the order of taking down the splenic ligaments should be determined by the anatomy and may vary from patient to patient. In fact, for acutely injured spleens, many of these ligaments may already be avulsed.

Preservation of the spleen should be considered in low-grade injuries if the patient is hemodynamically stable with a low overall injury burden. In cases with avulsion of the splenic capsule or minor lacerations, hemostasis can be achieved with electrocautery and local hemostatic agents. Splenic lacerations may be repaired with absorbable figure-of-eight or horizontal mattress sutures, on a blunt liver needle. The presence of an intact splenic capsule makes the placement of the sutures technically easier. If the parenchyma is fragile and does not hold sutures, pledgets may be used. An

absorbable splenic mesh can also be used (Fig. 25-15) as an adjunct to splenorrhaphy, especially in cases with multiple stellate parenchymal injuries.

Early local postsplenectomy complications include recurrent bleeding, pancreatic complications (pancreatitis, pseudocyst, and pancreatic fistula), gastric complications (gastroparesis, necrosis of the greater curvature), subdiaphragmatic abscess, splenic vein thrombosis, splenic arteriovenous fistula, left lower lobe atelectasis, or pleural effusion. Complications after splenorrhaphy include intrasplenic hematoma or abscess, splenic infarcts, and pseudoaneurysms or arteriovenous fistulas. A follow-up CT scan with intravenous contrast should be performed in all high-grade splenic injuries managed with splenorrhaphy. Early postsplenectomy hematologic changes include leukocytosis and thrombocytosis. The leukocytosis is usually moderate, rarely exceeding 16,000 to 18,000/mm³ and may last several weeks. More severe leukocytosis may indicate an infectious complication, especially in the presence of fever or tachycardia.⁵⁸ Thrombocytosis is usually moderate, may last for a few weeks and in most cases is clinically irrelevant.

Figure 25-15. Splenic preservation with use of an absorbably mesh bag. (With permission Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. New York, NY: Cambridge University Press; 2015.)

Postsplenectomy infections may occur early or late. There is evidence that splenectomy is associated with an increased risk of early postsplenectomy infections. A recent prospective observational, multicenter study of 269 patients with blunt splenic injury surviving at least 72 hours, reported that splenectomy had a significantly higher incidence of infectious complications than splenic preservation.⁵⁹ A regression analysis identified splenectomy as an independent risk factor for infectious complications.

Overwhelming postsplenectomy infection (OPSI) is a rare but life-threatening complication, especially in children. The reported mortality varies from 10% to 80%. Encapsulated organisms, such as *Haemophilus influenza*, *Streptococcus pneumonia*, and *Neisseria meningococcus* are the most common pathogens. Although the majority of infections occur within the first 3 to 4 years, OPSI may occur at any time after splenectomy. The Surgical Infection Society recommends that all splenectomized patients 2 to 64 years old receive the 23-valent pneumococcal vaccine.⁶⁰ In addition, high-risk patients should receive *Haemophilus influenza* and Meningococcal vaccines. The timing of administration of the vaccines after trauma may be optimal at 14 days after splenectomy.⁶¹ There is no evidence to support routine long-term prophylactic antibiotic administration in splenectomized patients. Patients should be educated on postsplenectomy sepsis, wear a medical alert bracelet, inform caregivers of their asplenic state, and be advised to seek medical care with the onset of any signs of infection.

PANCREAS

Anatomy

The pancreas is a retroperitoneal organ with its head directly situated over the inferior vena cava and its neck over the superior mesenteric vessels and the proximal portal vein. The body extends over the suprarenal aorta and the left renal vessels, closely related to the splenic artery and vein. The uncinate process wraps around the superior mesenteric vessels. As described for the spleen, the splenic vein courses inferior to the splenic artery and joins the superior mesenteric vein at a right angle to form the portal vein behind the neck of the pancreas. The inferior mesenteric vein drains into the splenic vein behind the body of the pancreas (Figs. 25-16 and 25-17).

The major pancreatic duct of Wirsung travels down the entire length of the pancreas and drains into the ampulla of Vater, approximately 8 cm downstream from the pylorus. The lesser duct of Santorini branches off the superior aspect of the major duct, at the level of the neck of the pancreas. This drains into the duodenum, approximately 2 to 3 cm proximal to the ampulla of Vater. The pancreatic head and the proximal duodenum receive their blood supply from the anterior and posterior pancreaticoduodenal arcades. Because these arcades lie on the surface of the pancreas, close to the duodenal loop, separating these can result in ischemic damage to the duodenum.

Figure 25-17. Pancreatic anatomy demonstrating relationship to stomach. (With permission Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. New York, NY: Cambridge University Press; 2015.)

Epidemiology

Pancreatic trauma is seen in approximately 0.2% of blunt trauma and about 1% of penetrating trauma patients. Overall, about 60% of patients with blunt trauma and about 90% with penetrating trauma will

have associated intra-abdominal injuries. The most commonly associated injury in blunt trauma is the spleen. Duodenal injuries are found in less than 10% of the patients. In penetrating trauma, the most commonly associated injuries are the stomach, closely followed by the liver. Associated intra-abdominal vascular injuries are common in penetrating injuries and are found in more than 75% of penetrating injuries to the head of the pancreas. A concomitant major vascular injury increases the likelihood of a poor outcome. The most widely used grading system (Table 25-3) is the OIS-AAST.⁴⁵ The classification is based on CT and operative findings.

Table 25-3 OIS-AAST Grading Scale for the Pancreas

Grade ^a	Type	Injury Description
I	Hematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Hematoma	Major contusion without duct injury or tissue loss
	Laceration	Major laceration without duct injury or tissue loss
III	Laceration	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal transection or parenchymal injury involving ampulla
V	Laceration	Massive disruption of pancreatic head

^aAdvance one grade for multiple injuries to the same organ.
Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. *J Trauma* 1990;30:1427–1429.

Diagnostics

The diagnosis of penetrating pancreatic injury is usually made intraoperatively. The diagnosis in blunt trauma, especially for isolated injuries, may be difficult because the initial symptoms may be occult. Clinical signs may take hours or even days to manifest. Serial serum amylase and lipase levels may be useful as a screening test for pancreatic trauma but isolated values have poor sensitivity and specificity. Contrast-enhanced CT scan (Fig. 25-18) is the investigation of choice in suspected pancreatic trauma.^{62,63} Its accuracy increases with time from injury and in cases with an equivocal initial test, a repeat CT scan 6 to 8 hours after the initial investigation should be considered. MRCP or ERCP can be considered in selected cases with pancreatic trauma to establish the integrity of the pancreatic duct.^{64,65}

Figure 25-18. CT image of pancreatic transection after blunt trauma. Oval demonstrates the pancreatic transection.

Treatment

The management of pancreatic trauma is determined by the mechanism of injury and the presence or absence of pancreatic duct injury. All penetrating injuries require operative management. However, most patients with isolated blunt trauma to the pancreas with an intact pancreatic duct can safely be managed non-operatively. A National Pediatric Trauma Registry study of pancreatic injuries in 154 children, reported that non-operative management was successful in approximately half of high-grade injuries and in approximately 80% of low-grade injuries.⁶⁶ Other studies have confirmed the safety and

high success rate of non-operative management in children.^{67,68} The success rate of non-operative management in adults however is significantly lower, in part due to the higher incidence of pancreatic duct injury which is less than 1% in children, but approximately 15% in adults. The safety of selective non-operative management in adults has been confirmed in many studies.^{69,70}

Non-operative management is safe for low-grade injuries and many selected higher-grade injuries, especially in children. For higher-grade injuries, the integrity of the pancreatic duct should be evaluated with ERCP or MRCP. ERCP can also be therapeutic with pancreatic duct stent placement, as definitive treatment. Complications associated with non-operative management include pancreatic pseudocyst and pancreatitis. There is no evidence that the use of somatostatin analogs increases the success rate of non-operative management and they should not be used routinely.

For patients undergoing operative management, the pancreas is exposed through the lesser sac. This allows access to the anterior, superior, and inferior surfaces of the body and tail of the pancreas. The posterior aspect of the pancreas can be mobilized by incising the peritoneum over the inferior border of the pancreas and retracting upward. If more extensive mobilization is required for the distal pancreas, this can be achieved by en-block mobilization and medial rotation of the spleen and tail of the pancreas. For the head and uncinate processes, exposure is achieved with an extended Kocher maneuver.

As a general rule, all peripancreatic hematomas should be explored to examine for any underlying ductal injuries. However, hematomas localized to the head of the pancreas may be left undisturbed, because the duct in this area is deep in the parenchyma and exploration is difficult and potentially dangerous. These injuries should be drained externally with closed drains and postoperatively the integrity of the duct can be evaluated using MRCP or ERCP and treated with stenting.^{65,71}

Low-grade injuries without obvious ductal disruption should be treated with the debridement of nonviable tissue, hemostasis, and wide external drainage. For severe parenchymal injuries with known or suspected ductal disruption, the optimal procedure will depend on the condition of the patient and the site of the pancreatic injury (head and neck vs. tail). Severe pancreatic injuries involving the body to the left of the superior mesenteric vessels are best treated by distal pancreatectomy, with or without splenic preservation (Fig. 25-19). For destructive injuries to the head of the pancreas, especially with concurrent duodenal injury, if the operative procedure is to undergo damage control, or if this is beyond the skill set of the operating surgeon, the safest option is hemostasis and external drainage. Damage control packing and temporary abdominal closure with delayed resection and reconstruction can be performed. If however, a pancreaticoduodenectomy is to be performed, even for hemodynamically stable patients with an experienced surgeon, a two-stage procedure is highly recommended. The initial operation includes temporary control of bleeding by means of packing and in the appropriate cases, arterial shunting or if there is a concomitant venous injury, ligation. The duodenal and pancreatic head resection is performed and the common bile duct is ligated or drained externally. The definitive reconstruction should be performed only after normalization of the patient's physiology. The reconstruction, which includes pancreaticojejunostomy, choledochojejunostomy, and gastroenterostomy, is similar to that in elective cases and should be performed with expert assistance in an optimized patient.

Figure 25-19. Distal pancreatectomy specimen with splenectomy specimen after blunt trauma.

Pancreas-related local complications occur in about 25% of patients and include pancreatic fistulas, pseudocysts, pancreatitis, and perihepatic infection. Most of these complications can successfully be managed non-operatively or with percutaneous drainage and endoscopic stenting of the duct.⁷¹ Endocrine and exocrine pancreatic insufficiencies may occur after major pancreatic resections, but the true incidence of this remains unknown. Patients undergoing major pancreatic resections should be

monitored on a regular basis, at least during the first few months after the operation. For those who underwent a pancreaticoduodenectomy and survived, late stricture of the choledochojejunostomy is not uncommon, because of the small size of the common bile duct. The stricture may manifest many months after the operation and thus it is recommended that these patients are followed regularly, especially during the first few months after the injury.

STOMACH

Anatomy

The stomach is a hollow viscus organ located in the left upper quadrant of the abdomen with the fundus, GE junction, and often a significant portion of the body lying above the costal margin. The stomach has a robust blood supply including the left and right gastric arteries, the right and left gastroepiploic arteries, and the short gastric arteries. This level of vascularity can result in significant bleeding after injury but also provides redundancy, making devascularization and necrosis of the stomach relatively rare after trauma.

Diagnostics

Gastric injury usually results from either significant blunt force trauma or after penetrating trauma to the left upper abdomen or lower chest. Presence of blood upon placement of an NG tube is concerning for gastric injury. The majority of patients with full-thickness gastric injury after trauma will present with spillage of gastric contents and peritonitis resulting in direct transfer to the operating room. Blunt injury to the stomach can cause local contusion with gastric wall hematoma or hollow viscus rupture, similar to bladder rupture, with a large full-thickness defect.

After blunt or penetrating trauma, in the absence of peritonitis or hemodynamic instability, additional diagnostic workup with CT imaging is appropriate. CT scan findings concerning gastric injury include extraluminal contrast, air, blood, or fluid, or localized thickening, or enhancement and discontinuity of the gastric wall.⁷²⁻⁷⁴

Treatment

Gastric repair is generally well tolerated due to the redundancy of tissue and blood supply of the stomach. After penetrating injury, if a single gastric injury is identified, the operating surgeon must assume there is an additional injury corresponding to the entry or exit site. A single gastric injury is exceedingly rare and even a linear laceration should not be mistaken for a tangential wound unless meticulous inspection has ruled out an additional enterotomy. The anterior border of the stomach is fully inspected from the esophagus to the pylorus. The left lobe of the liver may need to be retracted or mobilized for better visualization of the proximal third of the stomach. The posterior aspect of the stomach is evaluated by accessing the lesser sac below the gastroepiploic vessels. The posterior gastric wall must be fully evaluated and visualized all the way up to the GE junction to avoid missed injury. Blood or fluid upon entry into the lesser sac should alert the surgeon to a likely gastric and/or pancreatic injury. Care must be taken when inspecting the GE junction and greater curvature not to apply excess tension on the gastric fundus as this may result in iatrogenic splenic capsular tear or laceration.

Low-grade injuries including hematomas and contusions should be evaluated and evacuated as appropriate. After hematoma evacuation and hemostasis is achieved, the area may be reinforced with Lembert sutures. Full-thickness injuries can be repaired in one or two layers. A two-layered repair includes an inner layer of running absorbable suture and an outer layer of Lembert sutures. Injuries of the greater curvature or larger injuries of the body can be controlled with a stapling device and wedge resection. In gunshot injuries, it is important to debride the devitalized tissue surrounding the injury prior to repair. Given the tissue redundancy of the stomach, stapling devices may be used liberally for wedge resection. Care must be taken, however, to avoid narrowing the GE junction or pylorus. Injuries involving the pylorus may be incorporated into a pyloroplasty for repair.

Significant destructive injuries or those involving the GE junction or pylorus may require a proximal or distal gastrectomy with reconstruction. In rare cases, a total gastrectomy with esophagojejunostomy is required. Proximal gastric injuries or those at the GE junction may present a technical challenge for surgeons not accustomed to these operations. Attempts to repair these complex injuries without appropriate experience can lead to significant morbidity and mortality for the patient. In such cases, a

two-staged procedure should be considered. At the initial operation, the distal esophagus or proximal stomach may be stapled and internally drained with a nasogastric tube thus controlling the injury in a damage control manner. An additional staple line distal to the injury will prevent reflux contamination. The area may be drained and the patient stabilized with a delayed reconstruction performed under optimal conditions with all of the requisite expertise present.

DUODENUM

Anatomy

The duodenum is the first portion of the small intestine and forms a C-loop around the head of the pancreas. The duodenum is divided into four parts, an anatomic distinction that can help guide management of traumatic injury. The first portion is intraperitoneal and associated with the portal structures and the gastroduodenal artery. The second and third portions are retroperitoneal and curve around the head of the pancreas. The common bile and pancreatic ducts drain into the ampulla in the second portion of the duodenum. The fourth portion of the duodenum ascends to the ligament of Treitz to join the jejunum.

Figure 25-20. Gunshot injury to duodenum just proximal to the ligament of Treitz.

Epidemiology

Duodenal trauma is rare, occurring in less than 5% of all trauma patients, and is associated with a high morbidity and mortality.⁷⁵⁻⁷⁷ Patients with duodenal trauma frequently have additional intra-abdominal injury, most commonly of the liver, pancreas, and small bowel.

Treatment

Most low-grade duodenal hematomas secondary to blunt trauma without perforation can be managed conservatively with NG tube decompression and supplemental nutrition. The majority of duodenal trauma, however, is secondary to penetrating injury (Fig. 25-20) and is identified during operative exploration. Duodenal hematomas encountered intraoperatively require exploration to evaluate for underlying perforation.

Mobilization of the duodenum is most commonly achieved with a Kocher maneuver. This allows for medialization of the second and third portions of the duodenum, evaluation of the posterior wall, and exposure of the underlying vascular structures to examine for injury. Separation of the second portion of the duodenum from the head of the pancreas is not advised as disruption of the blood supply puts the duodenum at high risk of ischemia.

Most duodenal injuries can be repaired primarily in one or two layers with a transverse closure to avoid luminal narrowing. Segmental resection is rarely needed but, in the event of injury >50% of the duodenal circumference, resection with primary, end-to-end anastomosis may be performed when appropriate. Segmental resection is not recommended for the second portion of the duodenum due to the presence of the ampulla and inability to mobilize the medial wall. In complex injuries, pyloric exclusion with gastrojejunostomy may be utilized to protect the repair, however, routine exclusion should not be used for all duodenal injuries. In an analysis of 193 consecutive patients with duodenal injuries, pyloric exclusion offered no morbidity or mortality benefit over primary repair.⁷⁸ If performed,

external stapling of the pylorus with a TA stapler and internal cerclage with a suture are both acceptable techniques for pyloric exclusion. Most frequently, a gastrojejunostomy to restore continuity is performed. Additional surgical adjuncts include a serosal patch and duodenojejunostomy. In the unstable patient, damage control techniques may be safely applied to duodenal injury with delayed repair or diversion.⁷⁹ The traumatic Whipple is rarely indicated and carries a high mortality.^{80,81} This should be considered only in patients with complex destructive injuries to the duodenum and pancreas. In these cases, the provider should focus on a damage control procedure with control of contamination and associated hemorrhage as the goals of the index operation. The subsequent reconstruction should be performed in a stabilized patient, most commonly in a staged manner, with expert assistance available. Liberal use of closed suction drainage is recommended after duodenal injury and/or repair.

One of the major complications after duodenal injury repair is fistula formation, occurring in 4% to 33% of patients.^{76,79,82} These are managed, when possible, with percutaneous drainage. In rare cases, reoperation and repair or diversion is required.

COLON

Epidemiology

Colon injuries occur in approximately 30% of abdominal GSWs and 20% of SWs undergoing laparotomy. In blunt trauma, approximately 10% of patients undergoing laparotomy will have a colon injury. Many of the blunt trauma injuries are superficial with only 3% of patients undergoing laparotomy having a full-thickness perforation. The presence of an external seatbelt mark sign is associated with an increased risk of colon injury.

Diagnostics

The definitive diagnosis of colon injury is almost always made intraoperatively. Preoperative diagnosis of colon injury following blunt trauma is difficult, especially in unevaluable patients. If a CT is obtained, mesenteric stranding, bowel wall thickening, and unexplained fluid can be seen, increasing the level of suspicion for a bowel perforation. Free extraluminal air is rare. Intraoperatively, all colonic hematomas should be explored to rule out any underlying colon injury without devascularizing the wall. Particular care should be taken for penetrating injuries, especially due to shotgun wounds, where the injury can be hidden within the fat.

The severity of colon injury can be graded by the OIS-AAST colon injury scale (Table 25-4), which is based on the operative findings.⁴⁵ A practical classification used by many surgeons breaks injuries down into two severity groups, nondestructive injuries involving <50% of the bowel wall without devascularization versus destructive injuries which involve >50% of the bowel wall or demonstrate devascularization.

Treatment

The management of colon injuries has undergone major changes over the last two decades.^{83–85} For nondestructive injuries there is sufficient class I and class II evidence supporting primary repair irrespective of risk factors, such as the site of colon injury, associated injuries, or physiologic status.^{86–88}

For destructive colon injuries, defined as those with loss of >50% of the bowel wall circumference or with devascularization, segmental colonic resection is required. The management of these cases is controversial. These injuries were traditionally managed with diversion because of the perceived high risk for anastomotic leak and intra-abdominal sepsis. Although the safety of primary anastomosis was demonstrated in several small studies,^{86–88} for specific circumstances such as a penetrating abdominal trauma index ≥ 25 or hypotension or large-volume blood transfusions or patient comorbidities, the potential benefit of diversion remains unclear.^{88,89}

Table 25-4 OIS-AAST Grading Scale for the Colon

Grade ^a	Type	Injury Description
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration ≥50% of circumference without transection
IV	Laceration	Transection of the colon
V	Laceration	Transection of the colon with segmental tissue loss
	Vascular	Devascularized segment

^aAdvance one grade for multiple injuries to the same organ.
Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. *J Trauma* 1990; 30:1427–1429.

The Eastern Association for the Surgery of Trauma (EAST) guidelines based largely on class III evidence recommended that diversion be considered in patients with shock, significant associated injuries, peritonitis, or underlying disease.⁹⁰ Since these were published, a more recent American Association for the Surgery of Trauma prospective multicenter study examined 297 patients with penetrating colon injuries requiring resection.⁹¹ This was a prospective observational study examining the outcomes associated with diversion versus primary anastomosis without diversion. The overall colon-related mortality was 1.3% and all deaths occurred in the diversion group. The incidence of anastomotic leaks was 6.6%. Multivariate analysis identified severe fecal contamination, >4 units of blood transfusions within the first 24 hours, and antibiotic choice as independent risk factors for abdominal complications. The method of colon management, anastomosis, or diversion did not impact outcomes. In addition, delay of operation >6 hours, shock at admission, site of colon injury, penetrating abdominal trauma index >25, ISS >20, or associated intra-abdominal injuries were also found to have no association with a negative outcome. Based on the available data, for both blunt and penetrating destructive injuries, if the patient meets criteria for a damage control procedure, contamination control with stapling of the colon should be performed. Whenever possible, an anastomosis should be performed at the index operation, but this is only if the patient is able to tolerate the additional operative burden. For stable patients not requiring damage control, the anastomosis should be performed without diversion. The choice of a stapled versus hand-sewn anastomosis has been shown not to make a difference.⁹² In a prospective study of 207 patients undergoing resection and anastomosis, the leak rate was 7.8% for hand-sewn and 6.3% for stapled anastomoses. For edematous bowel, often seen at the take back after an initial damage control resection, a hand-sewn anastomosis may be preferred.

Abdominal complications after colon injuries are common, with an abdominal sepsis rate of approximately 20%. Independent risk factors associated with an increased incidence of abdominal sepsis include fecal spillage, blood transfusions exceeding four units of blood within the first 24 hours, and the presence of chronic comorbid conditions. Retained bullets that have passed through the colon are not associated with an increased risk of infection and therefore their routine removal is not required.⁹³

Colonic leaks causing abdominal sepsis after repair or resection and anastomosis have been examined in detail. For primary repairs, in a review of 35 prospective or retrospective studies including 2,964 primary repairs, a leak rate of 2.2% was seen.⁹⁴ For patients undergoing resection and anastomosis, which are more likely to leak, the rate was 5.5%.⁹⁴ In the multicenter AAST study of 197 patients undergoing resection and primary anastomosis, the leak rate was 6.6%.⁹¹ Anastomotic leaks occur more commonly with a colon–colon anastomosis when compared to an ileocolic anastomosis. In the AAST study the leak rate was 4.2% for ileocolostomies and 8.9% for colocolostomies.⁹¹

The majority of leaks can be managed non-operatively with percutaneous drainage. They are usually small and seal off on their own. CT imaging should be obtained to examine for the presence of any intra-abdominal collections and to guide drainage. Reexploration of the abdomen for drainage and either fecal diversion or resection and reanastomosis is only required if the patient fails percutaneous drainage or develops evidence of generalized peritonitis.

For patients who require a colostomy, there is a significant complication burden associated with the colostomy itself as well as the subsequent closure. In a large series of 528 stomas performed in the trauma setting, approximately 22% of patients sustained an early complication and 3% a late complication.⁹⁵ In another study of 110 colostomy closures, a local complication rate of 14.5% was noted.⁹⁶

RECTUM

Anatomy

As the colon continues downstream, the rectum begins where the tenia coli coalesce as the terminal part of the large intestine. The rectum is approximately 12- to 15-cm long and is both intra- and extraperitoneal. Anteriorly, the upper two-thirds and laterally the upper one-third are intraperitoneal, with the lower third being completely extraperitoneal. The blood supply is derived from the superior rectal artery branching from the inferior mesenteric artery, the middle rectal artery from the internal iliac artery, and the inferior rectal artery which is from the internal pudendal artery.

Epidemiology

Most rectal injuries result from a penetrating mechanism, usually secondary to GSWs although anally inserted foreign body trauma and endoscopic trauma are also seen. Because of its protected location, blunt injury is only seen in approximately 5% to 10% of injuries, and is often associated with a pelvic fracture.

Diagnostics

The clinical presentation of rectal injuries that are intraperitoneal does not differ from that of colon injuries. For extraperitoneal injuries, the clinical symptomatology can be masked by containment of the perforation in the retroperitoneal tissues. As a direct consequence, operative exploration, direct visualization on anoscopy and sigmoidoscopy, or CT rather than clinical examination is used to make the diagnosis.

For blunt trauma patients, because the majority of injuries are in the intraperitoneal segment, the same diagnostic principles for colonic injuries apply. For penetrating injuries, both intraperitoneal and extraperitoneal injuries can occur. The diagnostic approach depends on the patient's clinical presentation. Patients with peritonitis, instability, or who are unexaminable should proceed directly to the operating room. For unstable patients, positioning should be supine with an emphasis on the laparotomy and hemorrhage control. Intraoperative sigmoidoscopy and anoscopy can be performed to examine the extraperitoneal segment of the rectum. For those that have peritonitis or instability, the patient may be placed in lithotomy to facilitate sigmoidoscopy and anoscopy. For those who are stable and who meet the criteria for a trial of non-operative management, the highest-yield initial examination is CT (Fig. 25-21). On the CT, the bullet trajectory is tracked. If the trajectory appears to traverse the rectum, the patient can be brought to the operating room, placed in lithotomy and a laparotomy performed. Preoperative or intraoperative sigmoidoscopy and anoscopy can be performed to examine the extraperitoneal segment of the rectum. If the tract is clear of the rectum on CT, no further investigations or treatment is required. For the equivocal CT scan where there is a questionable rectal injury, several options exist. The patient can be brought to the operating room for a laparotomy, sigmoidoscopy, and anoscopy. Another option is to perform diagnostic laparoscopy to look for intraperitoneal breach as well as a sigmoidoscopy and anoscopy. Any entry into the peritoneal cavity can then trigger a laparotomy and closer evaluation.

Figure 25-21. CT demonstrating a gunshot wound tract traversing the rectum, *arrow* demonstrates bullet tract.

For intraperitoneal injuries, the management principles are the same as those that apply to colon injuries. The vast majority undergo primary repair without the need for diversion. For extraperitoneal injuries, the management has evolved over the last decade. The classic approach to rectal injuries which included diversion, presacral drainage, and distal rectal washout is no longer performed.⁹⁷⁻¹⁰⁶

For distal extraperitoneal injuries that are accessible through a transanal approach, local repair can be performed without colostomy.^{99,105,106} For higher extraperitoneal injuries inaccessible in this manner, the primary treatment is fecal diversion without taking down the rectum and repairing the injury.^{103,104} This can even be done laparoscopically with a low rate of morbidity. In fact, the absolute need for colostomy has not even been demonstrated. Theoretically, diversion allows for decreasing the fecal flow past the unrepaired injury augmenting the healing process. Even after diversion, as there is some fecal flow past the injury at least initially during the early phases of healing, the true value of colostomy is questionable.

If there is an associated bladder injury, a tissue barrier using omentum should be placed between the suture lines as a method of decreasing rectovesical fistula formation, a complication seen in upward of a quarter of patients with combined injuries.¹⁰⁷ In the rare case where there is a combined destructive anorectal injury (Fig. 25-22), acutely, hemostasis and diversion are recommended. Once the patient has been stabilized, assessment of the anal sphincter function should be performed, and semielective reconstruction should be performed by a colorectal specialist.

Figure 25-22. Large perineal and groin avulsion injury after pedestrian struck by train.

Chapter 26

Genitourinary Trauma

Hunter Wessells

Key Points

- 1 Upper urinary tract injury is an infrequent result of trauma and the majority result from blunt mechanism.
 - 2 Renal injury after blunt trauma requires further evaluation for all cases of gross hematuria; cases of microscopic hematuria associated with an episode of hypotension in adults; significant microscopic hematuria in children.
 - 3 Renal imaging is required with any degree of hematuria after penetrating trauma.
 - 4 Most renal injuries are managed nonoperatively, with indications for exploration being symptomatic renal hemorrhage causing hypotension, expanding or pulsatile retroperitoneal hematoma at laparotomy, and grade V injury.
 - 5 Ureteral injuries due to external violence are rare and require CT imaging or direct exploration; missed injuries are common due to lack of consistent physical findings.
 - 6 Injuries to the bladder require prompt diagnosis and catheter drainage, with intraperitoneal and complicated extraperitoneal injuries necessitating surgical repair.
 - 7 Initial management of urethral injuries varies based on location (anterior vs. posterior) and severity, the most severe requiring urinary diversion with suprapubic cystostomy.
 - 8 Immediate repair of urethral injuries in patients with complex pelvic fractures is not standard of care, and early endoscopic realignment should be undertaken only by a surgeon experienced with this technique.
-

The incidence of trauma is rising and the World Health Organization estimates that without change or intervention, road traffic injuries will be the sixth leading cause of death by the year 2020 worldwide.¹ Based on U.S. Census data, we estimate that 15,000 persons would sustain renal injuries requiring hospital evaluation annually. The number of bladder and urethral injuries is estimated between 5,000 and 10,000. While injuries to the genitourinary system as a whole are rarely life threatening, the potential morbidity is high and resultant effects on quality of life are marked. Genitourinary injuries have predictable clinical presentations, and imaging modalities have improved our ability to identify and treat these injuries. We review the fundamental principles guiding the evaluation and treatment of genitourinary trauma, including the American Urological Association *Practice Guidelines on Urotrauma*.² This recent publication incorporates a rigorous evidence review and standardized approach to guideline development.

UPPER URINARY TRACT INJURY

Kidney

Injury to the upper urinary tract (kidney, ureter) is rare following trauma, with an incidence of renal injury of 4.89 per 100,000 persons.³ Recognizing the factors that predispose to urinary tract injury facilitates early diagnosis and management, which is associated with improved outcomes. The majority of blunt traumatic injury is the result of motor vehicle collision, with fall and motor vehicle–pedestrian collision being second and third, respectively. Penetrating injury predominantly is due to firearm and less often stab wound.³ Findings on physical examination concerning significant renal injury include rib fracture, significant flank ecchymosis, and penetrating wounds of the abdomen, flank, or lower chest.² Anatomically, the kidneys lie in the retroperitoneum, surrounded by the ribcage, retroperitoneal fat, perirenal fat within Gerota capsule, and overlying viscera (right: liver, colon, duodenum, and adrenal;

left: spleen, colon, adrenal, and pancreas). Injury may occur as a result of interaction of the surrounding “protective” bony and soft tissue structures with the kidney.⁴ The collecting system begins within the kidney, forms the renal pelvis and concentrically narrows at the ureteropelvic junction (UPJ) to become the ureter. The ureter then traverses the retroperitoneum inferiorly, protected by retroperitoneal fat and the psoas muscle. After crossing over the common iliac vessels, the ureter descends into the pelvis, coursing caudad to the base of the bladder, entering the trigone obliquely at the ureterovesical junction (UVJ).

1 Hematuria is the most sensitive clinical sign of renal injury, yet the degree does not predict injury severity (an algorithm for the evaluation and management of renal trauma is shown in [Algorithm 26-1](#)). Clinicians should perform diagnostic imaging with intravenous (IV) contrast-enhanced computed tomography (CT) to identify significant renal injuries in blunt trauma patients with (1) gross hematuria or (2) microscopic hematuria, and any recorded systolic blood pressure <90 mm Hg.² Penetrating injuries with any degree of hematuria or a trajectory in proximity to the kidney also require imaging if the patient is hemodynamically stable. Imaging decisions in hemodynamically unstable patients require close coordination with the trauma surgery team and are beyond the scope of this chapter (see similar chapter on GSW to abdomen). CT provides the most accurate staging of upper urinary tract injuries and corresponds closely with the American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS) ([Table 26-1](#), [Fig. 26-1](#)).⁵ The scan consists of early venous phase contrast-enhanced images, detecting intravascular contrast extravasation (ICE), renal parenchymal perfusion and integrity, and perinephric and retroperitoneal hematoma. Delayed (5 to 10 minutes) imaging is essential for identifying the collecting system injury (urinary extravasation, hydronephrosis) and ureteral continuity to the bladder. The use of intravenous urography to stage injuries is limited because of lower accuracy for clinical staging.^{2,6} Focused abdominal ultrasound for trauma (FAST) is used primarily to detect intraperitoneal bleeding in unstable blunt trauma patients; its use for detecting urologic injury is inferior to CT.⁷⁻⁹ Renal arterial angiography should not be used diagnostically, but therapeutically is indicated to treat isolated, symptomatic (early or late) renal bleeding, arteriovenous fistula, or pseudoaneurysm using embolization.¹⁰

Algorithm 26-1

Algorithm 26-1. Algorithm for the evaluation and management of renal injury.

2 Grade I and II injuries rarely require further management. The bulk of blunt grade III and nonvascular grade IV injuries should be managed nonoperatively, whereas only selected penetrating injuries in hemodynamically stable patients can be managed on observation protocols.^{11,12} Lacerations with associated collecting system injury (i.e., grade IV) can initially be managed with observation, although a subset of patients will require ureteral stenting due to persistent urinary extravasation. A proposed modification to the AAST OIS stratifies major renal lacerations into “high risk” and “low risk” based on the likelihood of intervention for hemodynamic instability.¹³ The CT imaging criteria of ICE, medial parenchymal laceration, and perirenal hematoma rim distance >3.5 cm have been validated to predict the need for intervention and may lead to further refinement in nonoperative management.¹⁴

3 The surgical team must perform immediate intervention (surgery or angioembolization in selected situations) in hemodynamically unstable patients with no or transient response to resuscitation.² Unstable patients will usually be found to have an expanding or pulsatile retroperitoneal hematoma at laparotomy, and occasionally have hilar injury or pedicle avulsion. In patients undergoing laparotomy for concomitant intraperitoneal injuries, exploration should only be considered judiciously for grade III or IV renal injury due to higher rates of nephrectomy under such circumstances.¹⁵ If renal exploration is contemplated or necessary, demonstration of contralateral renal function is important in the event of ipsilateral nephrectomy. This can be achieved by manual palpation or preferably by intraoperative single-shot intravenous urogram (KUB 10 minutes following intravenous injection of 2 mL/kg contrast).⁶ Reasons for failure to demonstrate contrast excretion from the contralateral kidney may indicate solitary kidney, hilar injury, hypoperfusion, or global renal insufficiency secondary to chronic renal disease. Exploration of a solitary kidney should be performed only when absolute indications exist.

Table 26-1 American Association for the Surgery of Trauma Organ Injury Scale

Injured Structure	AAST Grade	Characteristics of Injury
Kidney ^a	I	Contusion with microscopic or gross hematuria, urologic studies normal; nonexpanding subcapsular hematoma without parenchymal laceration
	II	Nonexpanding perirenal hematoma confined to renal retroperitoneum; laceration <1 cm parenchymal depth of renal cortex without urinary extravasation
	III	Laceration >1 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
	IV	Parenchymal laceration extending through renal cortex, medulla, and collecting system with urinary extravasation; injury to main renal artery or vein with contained hemorrhage
	V	Completely shattered kidney; avulsion of renal hilum that devascularizes kidney
Ureter ^a	I	Contusion or hematoma without devascularization
	II	<50% transection
	III	50% transection
	IV	Complete transection with <2 cm devascularization
	V	Avulsion with >2 cm devascularization
Bladder ^b	I	Contusion, intramural hematoma; partial-thickness laceration
	II	Extraperitoneal bladder wall laceration <2 cm
	III	Extraperitoneal bladder wall laceration >2 cm or intraperitoneal bladder wall laceration <2 cm
	IV	Intraperitoneal bladder wall laceration >2 cm
	V	Intraperitoneal or extraperitoneal bladder wall laceration extending into bladder neck or ureteral orifice (trigone)
Urethra	I	Contusion with blood at urethral meatus and normal urethrography
	II	Stretch injury with elongation of urethra, but without extravasation of urethrography contrast material
	III	Partial disruption with extravasation of urethrography contrast material at injury site with visualization in the bladder
	IV	Complete disruption with <2 cm urethral separation and extravasation of urethrography contrast material at injury site, without visualization in the bladder
	V	Complete transection with 2 cm urethral separation or extension into the prostate or vagina

^aAdvance one grade for multiple injuries, up to grade III.

^bAdvance one grade for multiple injuries, up to grade III.

Adapted from Wessells H. Injuries to the urogenital tract. In Souba WW, Fink MP, Jurkovich GJ, et al., eds. *ACS Surgery*. 6th ed. New York, NY: WebMD; 2002;10:3.

The kidney and upper urinary tract are accessed through a midline abdominal incision, and the author obtains preliminary isolation of the renal vessels before renal exploration. Using the inferior mesenteric vein (IMV) as a landmark, a posterior peritoneal window is created medial to the IMV overlying the aorta, which allows access, dissection, and control of the proximal renal vasculature.¹⁶ When immediate nephrectomy is required, reflection of the right or left colon provides rapid access to the renal hilum.¹⁷ If this method is employed, manual compression followed by vascular clamping may be required. Renal cooling is not routinely employed due to time constraints and potential for worsening hypothermia. Once Gerota fascia is exposed and open, the kidney can be freed of its associated perinephric fat. The capsule of the kidney is routinely preserved for closure following renal reconstruction. During renal exploration, sharp debridement, hemostasis, collecting system repair, and bolstered closure of the renal capsule using absorbable suture is performed. A perinephric suction drain is placed away from the repair in the retroperitoneum and removed when drainage subsides, usually less than 50 mL/day. If concern exists as the nature of the drainage, an aliquot of fluid can be sent for creatinine concentration to evaluate for the presence of urine.

In the case of renal artery thrombosis, surgical revascularization is rarely helpful because of the time delay from injury to revascularization. Intervention is commonly limited to patients with solitary kidney or bilateral injuries.⁵ An emerging therapy is vascular stent placement across the injury or thrombosis; however, most series are limited and results mixed.¹⁸ Venous injuries often result in massive bleeding and may require nephrectomy. Isolated proximal left renal vein injuries can potentially be managed by ligation of the renal vein because collateral drainage is present via the gonadal, adrenal, and lumbar veins. Right renal venous injury requires repair, if feasible, or nephrectomy due to lack of collateral circulation.

Clinicians should perform follow-up imaging for renal trauma patients with deep lacerations (AAST grades III, IV, and V) and clinical signs of complications (e.g., fever, worsening flank pain, ongoing blood loss, and abdominal distention).² CT best delineates delayed bleeding, persistent urinary extravasation, urinoma, and infection.⁵ Secondary bleeding after nonoperative or surgical repair, which usually is caused by a pseudoaneurysm, should be managed angiographically. Ureteral stenting or percutaneous drainage is indicated for persistent leak or abscess. Late complications are uncommon and include renin-mediated hypertension from chronic renal ischemia, arteriovenous malformations, and

segmental arteriolar pseudoaneurysm.

Ureter

Ureteral injuries are rare (1%), with fewer than 10 presenting annually in busy trauma centers.¹⁹ These injuries often present without clear signs or symptoms, and many are missed at the initial assessment (an algorithm for the evaluation and management of ureteral trauma is shown in [Algorithm 26-2](#)). Clinicians should perform IV contrast-enhanced abdominal/pelvic CT with delayed imaging for stable trauma patients with suspected ureteral injuries.² In the adult population, gunshot wounds followed distantly by stab wounds are the most frequent source of injury associated with external violence.^{20,21}

4 Injury should be suspected when organs anatomically related to the ureter sustain injury: iliac vessels, bladder, colon, and lumbar spine or transverse processes. Significant deceleration and hyperextension mechanisms can result in ureteral avulsion as well. In children, the avulsion injury occurs at the UPJ due to increased hyperextensibility of the spine.

Figure 26-1. Grading of renal injury by computed tomography. A: Grade I, contusion; B: Grade II; C: Grade III; D: Grade IV, contrast extravasation; E: Grade V, devascularized.

Anatomically, the ureters begin posterior to the renal hilum at the UPJ. They course inferiorly through the retroperitoneum, along the anterior aspect of the psoas muscle. Upon entering the pelvis, the ureters run behind the gonadal vessels before crossing over the iliac vessels. Finally, the ureters continue caudally, and enter the inferior aspect of the bladder obliquely. The blood supply is segmental

and arises from the adjacent anatomic structures within the retroperitoneum and pelvis (proximal-lateral, mid/true pelvis-medial, and inferior-posteriolateral).

Often, patients with penetrating ureteral injuries undergo surgical exploration for associated injuries. Surgeons should directly inspect the ureters during laparotomy in patients with suspected ureteral injury who have not had preoperative imaging.² Traumatic ureteral contusions are best managed at the time of laparotomy with ureteral stenting or resection and primary repair depending on ureteral viability and clinical scenario.²

Algorithm 26-2. Algorithm for the evaluation and management of ureteral injury.

Surgeons should repair traumatic ureteral lacerations at the time of laparotomy in stable patients.² Debridement as indicated precedes ureter reconstruction, and the level and length of ureteral defect dictates the type of repair (Fig. 26-2). UPJ disruptions require formal reconstruction by reanastomosis or ureteropyelostomy. For injuries occurring in the proximal to midureter without associated renal injury, simple mobilization of the colon without hilar control can be used to expose the ureters. Short upper and midureteral injuries are repaired by primary repair or spatulated reanastomosis over a stent, whereas low pelvic ureteric injuries are repaired by ureteroneocystostomy (Fig. 26-3). A refluxing implant is acceptable in children and adults.

When patients are hemodynamically unstable, surgeons should elect temporary urinary drainage followed by delayed definitive management.² Damage control techniques for urinary diversion include debridement, drainage of the bladder and retroperitoneum, cutaneous ureterostomy diversion with a feeding tube, or ligation of the ureter with percutaneous nephrostomy tube placement.

Patients presenting with a delay in diagnosis often have symptoms of fever, flank pain, fullness, tenderness, atelectasis, or oliguria as a result of urinoma, hematoma, or abscess.¹⁹ Operative intervention at the time of delayed diagnosis can result in nephrectomy. Therefore, management options include ureteral stenting, nephrostomy tube placement, percutaneous urinoma drainage, and Foley catheter insertion. Reconstruction is planned at 3 to 6 months to allow for resolution of periureteral inflammation. Long-term complications of unrecognized ureteral injury include fistula, fluid collections, ureteral stricture, and obstructive uropathy.

Figure 26-2. Ureteral reconstruction by location of injury.

Figure 26-3. Techniques of ureteral repair. **A:** End-to-end ureteroureterostomy; **B:** Vesicopsoas hitch reconstruction with reimplantation performed by suturing of the bladder to psoas tendon after mobilization; **C:** Boari flap performed using a tubularized bladder flap based on the ipsilateral superior vesical artery; **D:** Transureteroureterostomy (TUU). For all repairs the principles include tension free, watertight, stented, spatulated, mucosa-to-mucosa anastomosis using absorbable suture with drain placement.

Individuals who have sustained major injury to the ureter require follow-up imaging in the form of renal ultrasonography, radionuclide scanning or CT urography to evaluate for development of stricture or fistula.¹⁹ Interval ultrasound to evaluate for urinoma or abscess is an acceptable imaging modality and limits radiation exposure.

LOWER URINARY TRACT INJURY

Bladder

Blunt trauma accounts for the majority of bladder injuries, with penetrating mechanisms comprising the remainder.²² Pelvic fractures are frequently associated with lower urinary tract injuries, although only 5 to 10% of pelvic fractures result in bladder injury.²³ In pelvic fracture two mechanisms predominate as causes of bladder injury, usually resulting in extraperitoneal rupture. The first involves shearing forces at deceleration resulting in injury at the fixed sites of pelvic fascial attachment. The second mechanism involves direct injury from pelvic bone fragments causing laceration of the bladder. Intraperitoneal blunt injury is due to rapid deceleration creating a rapid rise in intravesical pressure resulting in a “burst”-type injury. Extraperitoneal injuries account for 54% to 55% of bladder injuries, intraperitoneal injuries are 38% to 40%, and combined injuries account for 5% to 8%.²⁴ In the pediatric population, a larger proportion of injuries are intraperitoneal because of the relative intra-abdominal location of the bladder. However, the overall incidence is lower. The incidence of pelvic fracture is also lower in children, but, in contradistinction to adults, bladder neck injuries are more common in boys with a pelvic crush injury rather than urethral injuries as seen in adults.²⁵

Gross hematuria is a reliable sign occurring in 95% of patients with bladder injury. Imaging must be performed in the setting of gross hematuria and pelvic fracture, and should be performed when mechanism suggests injury or in the face of pelvic ring fractures and clinical indicators of bladder rupture (i.e. >30 RBC/hpf on urinalysis or physical findings).^{2,26} Isolated acetabular fractures without pelvic ring involvement do not need cystography without other indications.²⁶

Acutely, patients presenting with bladder injury may complain of inability to void or suprapubic pain, although these symptoms may be masked by pain from more significant injuries.²² With delayed presentation, frequent symptoms are abdominal distension, ileus, fever, or urinary ascites as a result of persistent leakage, pelvic urinoma, or abscess formation. Laboratory analysis demonstrates acidosis, hyperkalemia, hyperchloremia, hypernatremia, and uremia with intraperitoneal bladder injuries. Particular attention is paid to thorough evaluation of the lower urinary tract for concurrent injury, because of the frequency of these injuries with pelvic fracture. Penetrating and iatrogenic trauma to the pelvis or perineum generally results in associated visceral, urethral, or genital injuries, but without bony disruption.²⁷

Imaging of the bladder, if indicated, consists of retrograde cystography, and is performed in the clinically stable patient. For CT cystography, the bladder is filled retrograde with contrast and the scan is performed after 300- to 400-mL contrast is instilled. Static cystography remains an acceptable means of assessing for bladder rupture. Extraperitoneal contrast extravasation is confined to the pelvis on CT and appears as a “flame-shaped” opacity on static cystography (Fig. 26-4). Characteristic patterns of intraperitoneal contrast extravasation include pooling in the cul-de-sac, paracolic gutter, or retrohepatic space on CT or outlining of bowel loops on static cystography (Fig. 26-5).

Figure 26-4. CT cystography for intraperitoneal bladder injury.

Figure 26-5. CT cystography for extraperitoneal bladder injury.

5, 6 Surgeons must perform surgical repair of intraperitoneal bladder rupture in the setting of blunt or penetrating external trauma.² The size of these ruptures generally precludes nonoperative approaches. Uncomplicated extraperitoneal bladder injuries should be managed with catheter drainage. Surgeons should perform surgical repair in patients with complicated extraperitoneal bladder injury. These are considered complex in the following circumstances²: exposed bone spicules in the bladder lumen; rectal or vaginal lacerations; and bladder neck injuries. In the case of open reduction internal fixation of pelvic fracture or repair of abdominal injuries, clinicians should perform bladder repair.

Bladder exploration includes assessment of the bladder wall, bladder neck, and ureteral orifices, which are inspected through an anterior cystotomy or the laceration/injury itself. Sites of injury are closed in a two-layer running fashion using 2-0 synthetic absorbable suture. Urethral catheter drainage is sufficient in most cases.² Suprapubic catheter diversion is reserved for extensive bladder injuries in which ongoing bleeding or complex repairs require additional drainage. Closed suction drains are placed away from the site of repair and can be removed in 48 hours unless the drainage fluid demonstrates a creatinine level higher than serum. The urethral catheter is left in place for 7 to 10 days and removed following cystogram demonstrating a healed, watertight repair.

Urethra

The anatomy of the urethra varies throughout its course and is divided for practical purposes into the anterior and posterior segments (Fig. 26-6). The type of injury varies depending on the segment, but most commonly is due to blunt mechanism. Anterior urethral injuries are the result of straddle-type falls or blows to the perineum. Posterior urethral injuries are often associated with pelvic fracture and involve varying degrees of prostatomembranous distraction.²⁸ Female urethral injuries are uncommon and are usually associated with pelvic fracture.²⁹ Gross blood at the urethral meatus in males is the most reliable sign and warrants evaluation for injury (an algorithm for the evaluation and management of urethral trauma is shown in Algorithm 26-3). Further examination includes digital rectal examination evaluating for hematoma, bony spicules, hemoccult blood, or a “high-riding prostate.” These findings on examination and the presence of perineal ecchymosis or scrotal hematoma suggest anterior pelvic disruption and urethral injury. Females with vaginal bleeding and pelvic fracture should be evaluated for gynecologic as well as urethral injuries.

7 Clinicians should perform retrograde urethrography (RUG) in patients with blood at the urethral meatus after pelvic trauma.^{2,30} RUG is readily performed using portable fluoroscopy in the emergency

department or operating room. The fossa navicularis is occluded with the partially filled (2- to 3-mL) balloon tip of a Foley catheter, the penis is stretched, and contrast is gently injected to opacify the urethra. Oblique images are taken, when possible, to establish the absence of or the presence and location of extravasation, which is indicative of injury. If no extravasation is present, the catheter is advanced into the bladder. Clinicians should establish prompt urinary drainage in patients with pelvic fracture urethral injury.² Initial management involves urinary diversion with suprapubic cystostomy.

Figure 26-6. Urethral Injury. Normal retrograde urethrogram and urethral injury management by segment and mechanism of injury.

Clinicians may perform primary realignment in hemodynamically stable patients with pelvic fracture urethral injury.² Techniques of early endoscopic realignment show promise in potentially decreasing rates of stricture formation while providing equivalent results with regard to continence and erectile dysfunction.^{31,32} Early realignment is achieved employing endoscopes and fluoroscopy, then placing a catheter, by Seldinger technique, over a guidewire. Clinicians should not perform prolonged attempts at endoscopic realignment in patients with pelvic fracture urethral injury.² Whether a patient receives a suprapubic cystostomy or a urethral catheter as drainage, an appropriate plan of follow-up for tube changes, removals, and definitive reconstructive efforts is imperative, due to potential morbidities including infection, encrustation, hematuria, stricture and obstructive uropathy.

8 Anterior urethral injuries can be divided into blunt straddle-type injury and penetrating mechanisms. Surgeons should perform prompt surgical repair in patients with uncomplicated penetrating trauma of the anterior urethra.² In contrast, clinicians should establish prompt urinary drainage, usually via suprapubic cystostomy in patients with straddle injury to the anterior urethra.² Similarly, high-velocity injuries should be managed with suprapubic cystostomy and delayed reconstruction.³⁰

Chapter 27

Vascular Trauma

Adriana Laser, Shahab Toursavadkahi, and Todd E. Rasmussen

Key Points

- 1 Vascular disruption and hemorrhage is a leading cause of mortality and morbidity in the civilian and military setting.
 - 2 Vascular injuries are categorized as occurring from either blunt or penetrating mechanisms.
 - 3 Motor vehicle crashes are the main cause of blunt vascular trauma in the civilian setting.
 - 4 Examining the patient is the most important step in evaluation of suspected vascular injury.
 - 5 Hard signs of vascular injury suggest near or complete disruption of the vessel in question and include pulsatile bleeding, expanding hematoma, palpable thrill, audible bruit, and or evidence of acute ischemia distal to the injury site.
 - 6 Contrast-enhanced computed tomography angiography (CTA) is the most available and common imaging modality used in the emergency setting including the evaluation of patients suspected of having vascular trauma.
 - 7 In the trauma patient, hemorrhage leads to both the overall metabolic consequences of total-body ischemia and end-organ ischemia of the specific injured vessel.
 - 8 Damage control resuscitation involves allowing permissive hypotension with a goal of a palpable radial pulse (in patients without head injury).
 - 9 Elevated fascial compartment pressures can be due to reperfusion, hematoma, swelling from crush injury, or major fractures.
 - 10 When discussing neck trauma, there are three regions classically used to describe anatomic location. Zone I is below the cricoid cartilage, zone II is between the cricoid cartilage and the angle of the mandible, whereas zone III is above the angle of the mandible.
 - 11 Control of bleeding from vascular disruption within the torso is not readily amenable to control with direct pressure and is therefore referred to as noncompressible torso hemorrhage.
 - 12 Proximal and distal control is essential when managing suspected vascular injury.
-

BACKGROUND

1 Vascular disruption and hemorrhage is a leading cause of mortality and morbidity in the civilian and military setting.¹⁻³ Because of their proximate anatomic nature, arterial and venous injuries often occur in conjunction with one another and are often associated with injury to other vital structures. To optimally manage scenarios in which there is suspicion for vascular injury or cases in which clear evidence of vascular disruption exists, it is necessary to possess an understanding of the epidemiology and anatomic distribution of this injury pattern, considerations associated with different mechanisms and key tenants of diagnosis and management. The objective of this chapter is to familiarize the reader with current knowledge pertaining to the topic of vascular trauma including commonality of the problem, circumstances in which vascular injury occurs, and different approaches to diagnosis. Additionally, this chapter will provide guidance on the management of different patterns of vascular injury focusing on the categories of extremity, torso, and cervical.

EPIDEMIOLOGY AND MECHANISMS OF VASCULAR TRAUMA

The epidemiology of vascular trauma can be broadly categorized into contextual circumstances (military and civilian), mechanism of injury (iatrogenic, blunt, penetrating, blast, and combination injuries), and anatomical site or location of injury (extremity, torso, and junctional).

Wartime Vascular Injury

Contemporary data confirm that exsanguination is the major cause of death in wounded service personnel and that the prevalence of wartime vascular trauma seems to have increased markedly over the past century (Figs. 27-1 and 27-2).¹⁻³ Estimates from allied surgeons in World War I (WWI) suggested overall vascular trauma rates of 0.4% to 1.3%.⁴ DeBakey characterized vascular injury burden in World War II (WWII) as affecting 0.96% of all patients and for the Korean and Vietnam wars the rate of vascular injury was judged to be slightly higher at 2% to 3%.⁴⁻⁶

Coalition militaries engaged in recent combat operations in Afghanistan and Iraq have reported rates of vascular trauma higher than in the previously mentioned military campaigns.^{2,7-9} In a study reporting US military experience, White and colleagues analyzed vascular cases entered in to the United States Joint Theater Trauma Registry (JTTR) from 2002 to 2009 (Fig. 27-2).² Defining the denominator as battle-related injuries sufficiently severe to prevent return to duty in the combat theater, the specific incidence of vascular injury (defined as the *total incidence injury*) was found to be 12% (1,570 of 13,076 cases). The incidence of injuries requiring an operation (defined as the *operative incidence*) was found to be 9% (1,212 of 13,076 cases). Injuries were most common in the extremities (79%) followed by those in the torso (12%) and cervical regions (8%). Of extremity vascular injuries two-thirds were documented in the lower extremities (most commonly femoral artery) while one-third occurred in the upper extremities (most commonly brachial artery).² In the torso, the most frequently injured vessels were the iliacs (3.8%) followed by the aorta (2.9%) and subclavian arteries (2.3%), and inferior vena cava (IVC) (1.4%). In the neck, 109 carotid injuries accounted for 7% of the total.

Figure 27-1. The rate of vascular injury reported from the wars of the previous two centuries. (From White J, Stannard A, Burkhardt GE, et al. The epidemiology of vascular injury in the wars in Iraq and Afghanistan. *Ann Surg* 2011;253(6):1184–1189.)

In the study by White and colleagues, it was noted that the vascular injury burden in the extremities in Iraq and Afghanistan was similar to that noted in World War II, although the higher modern rate of cervical and aortic injury was attributed to increased survivability and shortened medical evacuation (MEDEVAC) times.^{2,8} Overall, the authors concluded that the rate of vascular injury in these modern wars was five times that previously reported from Vietnam and Korea (Figs. 27-1 and 27-2). It is important to note that many of these reports from the wars in Afghanistan and Iraq did not include nonoperative cases and were generally confined to descriptions of vascular cases identified in the theater of war. Other studies, including one by Fox and colleagues, document the rate of wartime vascular injury from the perspective of military hospitals back in the United States, which also account for injuries that were diagnosed in a delayed fashion (i.e., delayed presentation or diagnosis of fistula, pseudoaneurysm or occlusion). In characterizing rates among patients having been evacuated to the United States, Fox and colleagues⁹ described a 7% prevalence of vascular injury.

In a similar but smaller British study, Stannard and colleagues scrutinized records of 1,203 injured UK servicemen between 2003 and 2008.⁷ Unlike the US JTTR, the British dataset also included patients who were *killed in action* (KIA), that is those who died prior to reaching a treatment facility.⁷ In this study, it was reported that 110 (9%) of the cohort sustained injuries to named vessels, of which more than two-thirds had extremity vascular injuries. Blast wounds accounted for 54% and 76% of patients sustaining torsocervical and extremity wounds, respectively. Some 66 of the 110 died before surgical intervention could be undertaken, indicating the highly lethal nature of this wounding pattern. In particular, no patient with a combination of vascular injuries affecting more than one body region (torso, extremity, and cervical) survived to an operation.⁷ Cervical vascular injuries also proved lethal, with 13 of 17 patients succumbing. On the other hand, of 76 patients with extremity injuries, 37 survived to surgery with one postoperative death. Interventions on 38 limbs included 19 damage control procedures (15

primary amputations, 4 vessel ligations in a group with a median mangled extremity score of 9) and 19 definitive limb revascularization procedures (11 interposition vein grafts, 8 direct repairs), with a limb salvage rate of 84%. This study concluded that while limb salvage is achievable in casualties able to withstand revascularization, torso vascular injury is often not amenable to successful intervention.⁷

Figure 27-2. The rate of vascular injury reported during the wars in Afghanistan and Iraq. This specific rate refers to the 1,570 US service personnel identified within the Department of Defence Joint Theater Trauma Registry (JTTR) as having sustained vascular injury during the wars (between 2002 and 2009). Note that the overall rate of 12% is several-fold higher than the rate of vascular injury reported in previous wars. (From White J, Stannard A, Burkhardt GE, et al. The epidemiology of vascular injury in the wars in Iraq and Afghanistan. *Ann Surg* 2011;253(6):1184–1189.)

Civilian Population Vascular Trauma

The impact of vascular trauma in the civilian setting is less well characterized than that which occurs in conjunction with combat-related activities. Most societies are not afforded large trauma-specific data repositories or registries which allow characterization of this injury pattern. Even in the United States, which is served by the National Trauma Data Bank® (NTDB®) large-scale studies are limited in number and mostly retrospective. According to data from the National Center for Injury and Prevention, in 2011 in the United States, injuries accounted for 51.3% of all deaths among persons ages 1–44 years of age which is more deaths than those caused by noncommunicable and infectious diseases combined.¹⁰ There is a significant increase in the number of admissions for both general and vascular trauma as the number of motor vehicle accidents increases and traffic density grows. Fatalities stem mainly from motor vehicle accidents (32%), gunshot wounds (22%), and falls (9%). Vascular injuries represent 1% to 2% of total trauma patients but they account for more than 20% of all trauma-related deaths and have the highest utilization of resources among the trauma population.³

In 2010, Demetriades and colleagues characterized vascular injury in 22,089 patients, including children, drawn from a population of more than 1.8 million in the NTDB®.¹¹ Accepting reporting bias that accompanies analysis of such retrospective data, it was determined that the incidence of vascular injury (2002 to 2006) was 1.6%. Four-fifths of the injured were male and the average age was 34 years. Half of the patients (51%) sustained a penetrating mechanism; the top 4 mechanisms of injury were motor vehicle collisions, firearms, stab wounds, and falls. Just under a quarter of patients presented in hemorrhagic shock and over half had an Injury Severity Score of more than 15.¹¹ Abdominal and chest injuries accounted for more than 25% and 24% of the injury burden, respectively, with arm and leg injuries contributing 26% and 18%. Mortality among those with vascular trauma was 23% and vessels associated with the highest rates of amputation were the axillary (upper limb amputation rate of 6%) and popliteal arteries (lower limb amputation rate of 15%).¹¹

In other reports of vascular trauma from civilian centers in New York and El Paso, the rates of injury, in the context of all presenting to each trauma center, were 2.3% and 3.4%, respectively.^{12,13} These reports confirm the “at-risk demographic” to be young and male and demonstrate that mortality in those with vascular trauma is twice that of patients without this injury pattern. Not surprisingly, penetrating mechanisms seem to be overrepresented in patients with vascular injury. The El Paso authors reported that of patients with vascular injury, 40% had a penetrating mechanism whereas only 10% of those with nonvascular trauma were injured in such a manner.¹³ The largest single center study of vascular trauma in the United States was published from Houston in 1988.³ This study encompassed a 30-year period, describing 5,760 injuries in 4,459 patients and confirmed that the burden of vascular trauma was borne by young men (86% male gender of average age 30 years), 90% of whom had been injured by firearms (gunshot 52%; shotgun 7%) or knives (31%).³ The Houston study also showed that

the wounding pattern in civilian circumstances, even where ballistic penetrating injury is common, does not follow that seen in wartime. Torso and neck injuries accounted for two-thirds of all injuries, while lower extremity injuries (including the groin) comprised only 20%. Whereas very few soldiers with injuries to the large vessels of the abdomen are seen by military surgeons, trauma to the abdominal vasculature accounted for 34% of the injury cohort seen in Houston, a fact attributed to the maturation of the city's Emergency Medical Services.³

Mechanism of Vascular Trauma

2, 3 Vascular injuries are categorized as occurring from either blunt or penetrating mechanisms either of which can disrupt, to varying degrees of severity, the normal integrity of the layers of the blood vessel wall (intima, media, and adventitia). Blunt vascular trauma is produced by local tissue compression and/or acceleration–deceleration resulting in disruptive shear forces. Motor vehicle crashes are the main cause of blunt vascular trauma in the civilian setting and these patients usually have injuries to other areas of the body including extremity fracture or dislocation, brain injury, and injury to structures in the abdomen or thorax. Although a blunt mechanism is more commonly associated with torso vascular injury (i.e., aortic disruption), this mechanism is also recognized to be associated with a few specific extremity fracture or dislocation patterns near (e.g., posterior knee dislocation, tibial plateau fracture and supracondylar fracture of humerus) is a common location for vascular disruption.

Penetrating mechanisms typically result in direct injury of the vessel(s) causing either laceration or contusion of the wall as well as separation or destruction of soft tissues along the path of the object and those directly surrounding the vessel. Penetrating vascular injury may result from simple, low-velocity sharp objects (i.e., knife or glass), irregular fragments from explosives mechanism or higher velocity, and uniform munitions fired from a weapon. For the later of these, damage to the vessel and surrounding soft tissue often results from a concussive shockwave that is conducted through the tissues as the object moves through the body dissipating energy. Unlike closed blunt injuries, which more commonly affect torso vascular structures, penetrating injuries more commonly affect the extremity vasculature, and this mechanism mandates management of the associated soft tissue wound.

DIAGNOSIS OF VASCULAR INJURY

Physical Examination

4 Examining the patient is the most important step in evaluation of suspected vascular injury.^{14,15} Most vascular injuries can be diagnosed with this step if it is performed in an intentional manner, being cognizant of the mechanism and while making use of a few enabling tools such as blood pressure measurement, basic radiography, continuous wave Doppler, and ultrasound. The physical examination should include exposing and palpating the extremities assessing for evidence of extremity fracture or dislocation, penetrating soft tissue wound and/or hematoma. The extremity vascular examination should also include assessment of distal perfusion, examining the appearance of the extremities, and palpating for the presence of pulses. In addition to assessing for penetrating wounds, examination of the abdomen and thorax (front and back) is important to identifying blood or fluid in these cavities with palpation and auscultation. Similarly, the neck and cervical region should be examined for signs of penetrating wounds, the presence of carotid pulses and/or bruising or hematoma.^{14,15}

5 When considering physical evidence of vascular trauma, especially during in the extremities, it is useful to categorize it into hard and soft signs. Hard signs of vascular injury suggest near or complete disruption of the vessel in question and include pulsatile bleeding, expanding hematoma, palpable thrill, audible bruit, and or evidence of acute ischemia distal to the injury site. Depending on the degree of extremity ischemia, a patient may exhibit one or more of the classic six “P’s” including pulselessness, pain, pallor, paresthesia, paralysis, and poikilothermia. Soft signs of vascular injury suggest only partial disruption of the vessel in question and include the history or evidence of moderate hemorrhage that has stopped, trauma in proximity to a named vessel (i.e., certain fracture or dislocation patterns) (Figs. 27-3 and 27-4), diminished pulse distal to the site of injury, nonexpanding hematoma or severe bruising, and a peripheral neurologic deficit. Although torso vascular injury is more difficult to diagnose with just the physical examination, it should be suspected in patients with asymmetric arm pulses or pressures and those with severe hypotension and evidence of fluid in the peritoneum or thoracic cavity. As mentioned, patients having survived a high-speed motor vehicle crash or lengthy fall should be considered for a blunt aortic injury.^{14,15}

Adjuncts to the Physical Examination

Several simple, noninvasive tools exist which can greatly enhance one's ability to diagnose vascular injury starting with the blood pressure cuff and measurement of pressure in both arms. A persistent discrepancy of more than 20 mm Hg between arm pressures suggests a proximal vascular injury to the subclavian or axillary arteries. A plain chest radiograph is also quick and useful as an adjunct in the diagnosis of blunt aortic injury. The classic signs of this injury pattern include a widened mediastinum (greater than 8 to 10 cm), an apical cap, loss of the characteristic aortic nob, downward displacement of the left mainstem bronchus, and a pleural effusion. Although multiple rib fractures are not a sign of aortic injury itself, it is a marker of severe blunt injury with significant shear and should raise one's index of suspicion for injury to the thoracic aorta.

Figure 27-3. A,B: Radiographic images of a Gartland type III fracture of the right supracondylar humerus which is commonly associated with brachial artery injury.

Figure 27-4. Radiograph of right upper extremity showing open humerus fracture and a temporary vascular shunt in the brachial artery which was severed by the fracture. The temporary vascular shunt was placed as a damage control adjunct to restore perfusion prior placement of the external fixator and patient evacuation to a higher echelon of care.

Continuous wave Doppler – with or without a manual blood pressure cuff – is another adjunct to the physical examination of patients in whom there is a concern for vascular injury. Doppler signals in the

distal extremity should be recorded as present or absent and, if present, graded as strong and bi- or triphasic or weak and monophasic.^{16,17} In the lower extremity, signals should be assessed in the dorsalis pedis and posterior tibial arteries while in the upper extremity, signals should be examined over the radial, ulnar, and brachial arteries. While describing the quality of Doppler signals can be somewhat subjective, identifying the presence of extremity perfusion by noting even the presence of an arterial signal is an important step that is typically less subjective than palpation for a pulse with one's finger.

The best use of continuous wave Doppler in the evaluation of the extremity is in conjunction with a manual blood pressure cuff, which allows one to record an arterial occlusion pressure adding a degree of sensitivity and objectivity to the process. In these instances, the blood pressure cuff is positioned on the distal portion of the lower or upper extremity (leg or forearm, respectively) proximal to the arteries which are to be examined. The Doppler probe is placed over a distal artery in the injured extremity until the arterial signal is audible. At this point, the blood pressure cuff is inflated to the point at which the signal is no longer present. The pressure at which the Doppler signal disappears is recorded as the arterial pressure in that extremity. This ankle or wrist pressure is then compared with the occlusion pressure of the arterial signal in another, noninjured extremity and the ratio of the occlusion pressure in the injured compared to that in the noninjured extremity is recorded as the injured extremity index or IEI. When comparison of arterial occlusion pressures is performed for a lower extremity injury – comparison of the lower to the upper extremity – it can also be referred to as the ankle-brachial index (ABI). The normal ABI or IEI is 0.9 or greater although caution should be used in interpreting the ratio in patients who are hypotensive, in severe pain, or hypothermic.^{15–17} Peripheral vasoconstriction is a normal response to significant trauma and shock and may result in a transiently decreased ABI or IEI in the absence of an injured axial vessel. In this context, assessment of the Doppler occlusion pressures and measurement of ratios should be viewed as dynamic and repeated after resuscitation, administration of pain control, and/or rewarming.

Ultrasound is another noninvasive modality that can be used in the evaluation of patients for vascular trauma. Brightness or B-mode ultrasound is ubiquitous in most emergency departments and critical care settings and allows one to make basic assessments that provide insight into the presence and severity of some patterns of vascular injury.^{14,15} The focused assessment with sonography for trauma or FAST examination of the abdomen is based on B-mode ultrasound and is commonly used to determine the presence or absence of fluid in the peritoneum following severe injury. Although not specific for vascular injury, if the FAST examination is positive in a patient who is severely hypotensive following trauma, one can deduce that the fluid is blood. In these cases, ultrasound is identifying the result of vascular disruption from within the parenchyma of a solid organ (liver, kidney, or spleen), a larger named vessel or some other source within the abdomen.

Duplex ultrasound combines B-mode imaging with pulsed Doppler and provides a more sensitive and specific method of assessment for vascular trauma. Duplex is less practical in the immediate or initial physical examination as these machines are typically less prevalent than basic Doppler or ultrasound and they traditionally require more technical support to perform (i.e., vascular technician). Increasingly, small and mobile ultrasound machines in the acute care setting are incorporating duplex into their platforms allowing for more widespread use of this diagnostic modality without the restrictions that traditionally limited its application. If available, duplex is particularly useful in evaluating the extremity and cervical vasculature and provides not only a B-mode image of the vessel lumen but also an assessment of the direction and velocity of flow. A full description of the capability and performance of Duplex ultrasound is beyond the scope of this chapter. However, it is an incrementally more powerful diagnostic, surveillance, and follow-up tool as it relates to vascular trauma and gaining familiarity with its use is recommended.

Computed Tomography and Magnetic Resonance Imaging for Vascular Trauma

Contrast-enhanced computed tomography angiography (CTA) and magnetic resonance imaging (MRI) or angiography (MRA) are sensitive tools used in the diagnosis of vascular trauma.¹⁸ The relative ubiquitous nature of these modalities means that they are often performed in severely injured patients as a matter of routine or screening (i.e., “pan-scan”) and not for the specific diagnosis of suspected vascular injury. In this context, practitioners must be aware of incidental CTA findings not correlated with the clinical case or mechanism of injury. In these cases, the incidental finding must be acknowledged but should also be put in context of the mechanism and pattern of injury, the history and physical examination, and the surgeon's overall clinical experience. From the standpoint of diagnosis of suspected vascular injury, CTA and MRA are most useful in patients with soft signs on physical

examination or those who have a high-risk mechanism or patterns of trauma.¹⁸

6 Contrast-enhanced CTA is the most available and common imaging modality used in the emergency setting including the evaluation of patients suspected of having vascular trauma. Multidetector CTA with high-speed helical scanning has reduced the time required to conduct the imaging and improved image quality. CTA has a high degree of sensitivity in identifying vessel dissection (i.e., separation of layers of the vessel wall), occlusion (i.e., thrombosis), and/or extravasation of blood into a contained space (i.e., pseudoaneurysm) or into an open space or cavity. CTA is particularly useful in the assessment of anatomic regions where physical and Doppler examination of the vasculature is limited (i.e., the torso, cervical and junctional regions). There is growing experience with CTA in the assessment of the peripheral vasculature and several clinical reports now demonstrate this modality's sensitivity and specificity in the diagnosis of extremity vascular injury.¹⁹ Extremity CTA is appealing for the polytrauma patient who has soft signs of vascular injury as it can be accomplished concurrent with imaging of other body regions (i.e., head, neck, abdomen, and pelvis).¹⁹

MRI or MRA also possesses a high degree of sensitivity as it relates to the diagnosis of vascular trauma. However, the more cumbersome nature of MRA, including the slower acquisition and interpretation of images makes it less well suited for use in the acute and early phases of trauma care. Currently, MRA is mostly reserved for select cases of cervical vascular injury (i.e., carotid and vertebral) in which CTA is equivocal or in which there is a significant intracranial component of the injury or its sequela (i.e., stroke). Although contrast-enhanced MRA of the extremity vasculature has excellent definition, it thus far offers no significant practical advantage over other proven modalities such as duplex ultrasound, CTA, or conventional contrast arteriography.

Contrast Angiography

Angiography is the direct imaging of any vascular structure using a contrast agent with fluoroscopy while arteriography and venography refer specifically to imaging of arteries or veins, respectively. Like CTA, angiography is often most useful in patients with soft signs of vascular injury or those having sustained a particularly high-risk injury mechanism. Angiography can be useful in patients with hard signs of vascular injury and in this scenario is often used as an intraoperative technique in those taken immediately to the operating room for surgical repair. Unlike CTA, this imaging modality is more invasive and requires a higher level of technical expertise to accomplish. However, contrast arteriography has the advantage of being able to be performed in the operating room at the time during which resuscitation can be accomplished and other injuries addressed.²⁰ Contrast angiography also has the advantage of being a precursor for endovascular therapies such as embolization and placement of covered stents or stent grafts.

Intravascular injection of contrast agents allows visualization of anatomy and can be accomplished after direct vascular puncture and placement of a needle or an endovascular catheter. Basic angiographic techniques should be a standard part of any general, trauma, and vascular surgical practice and are typically applied in the resuscitation or operating room. Diagnostic studies and interventions are also performed by radiologists in specialized imaging suites. Transcatheter or catheter-based arteriography provides the highest-resolution imaging of most vascular beds including anatomic definition and a road map for surgical planning or intervention (open or endovascular). Vascular injury can be demonstrated as extravasation of contrast if bleeding from the vessel(s) is brisk and ongoing. However, extravasation may not be visualized if the bleeding is slow or under tamponade. Bleeding may also be missed if the contrast bolus is too small, if it is injected into a different vessel, or if image acquisition is terminated too soon. Angiographic interruption of vessel continuity usually indicates disruption or occlusion (i.e., thrombosis). With sufficient contrast, distal reconstitution of flow (i.e., beyond the disrupted segment) from collateral vessels can typically be demonstrated. Imaging of distal arterial beds can be compromised by hypoperfusion and vasoconstriction, typical manifestations of shock. Vasospasm, with tapering of arteries (sometimes to occlusion) and slow flow, can be more prominent in young patients who have a greater degree of vasomotor reactivity.^{18,20}

Early venous filling after intra-arterial contrast injection indicates the presence of an arteriovenous fistula. Traumatic pseudoaneurysms result from focal disruption of arterial-wall integrity, with blood flow contained by adventitia or surrounding tissues. A pseudoaneurysm appears as a focal outpouching of contrast beyond the normal artery wall. Intimal flaps and focal segments of nonocclusive thrombosis may be detected as filling defects or lucencies within the contrast column, sometimes with a delay in distal contrast flow.

MANAGEMENT OF THE PATIENT WITH VASCULAR TRAUMA

Trauma Patient Pathophysiology

7 In the trauma patient, hemorrhage leads to both the overall metabolic consequences of total-body ischemia and end-organ ischemia of the specific injured vessel. Ischemia of both types results in anoxic cell death. Resuscitation is directed toward minimizing ischemia and the “lethal triad” of acidosis, hypothermia, and coagulopathy. Hypoperfusion, or ischemia, leads to acidosis, which causes platelet morphology changes and dysfunction and declining coagulation factor activity leading to decreased thrombin generation and the degradation of fibrinogen. Resuscitation with 0.9% NaCl also leads down a similar path of acidosis. Hypothermia likewise causes platelet dysfunction, less coagulation factor activity, and the induction of fibrinolysis. Both of these pathways lead to coagulopathy and endothelial damage. Nonbalanced massive blood transfusions can also lead to tissue injury, hypoperfused vascular beds, hemo dilution, and depletion/dilution of clotting factors and platelets, which can all contribute to a coagulopathic state.

Counterintuitively, the goal of resuscitation and repair, reperfusion, can precipitate another slew of metabolic insults on the trauma patient. Reperfusion ischemic tissues releases reactive oxygen species and sets off multiple proinflammatory processes including lipid peroxidation. This causes injury to the microvasculature which increases cell permeability and edema. An increase in interstitial pressure in turn leads to more stasis in microvasculature and therefore worsened ischemia. Ensuing cell lysis (e.g., rhabdomyolysis) leads to hyperkalemia, metabolic acidosis, and eventually myoglobin-induced renal failure.

Resuscitation of the Trauma Patient

After the usual ABCD is completed and an inventory of injuries is initially acquired, priorities of injury management can be set. Physical examination should include assessment for hard and soft signs of vascular injury. Examination can be performed almost simultaneously with plain radiographs when needed. General hard signs include active pulsatile bleeding or shock from blood loss, expanding/pulsatile hematoma, pulselessness, audible bruit over an artery, and palpable thrill. Hard signs mandate immediate trip to the OR for hemorrhage control and/or restoration of flow to the ischemic limb. These patients should not have CT/CTA done except in special cases. Unnecessary imaging delays definitive care and worsens outcome. If needed, on-table angiography can be used. Soft signs can include history of hemorrhage prearrival, venous ooze, nonexpanding/nonpulsatile hematoma, neurologic abnormality or decreased pulse as compared to contralateral limb, delayed capillary refill, and other additional site-specific signs. Venous access is also part of the initial management of the trauma patient. Large-bore catheters in peripheral veins of uninjured extremities are ideal, and preferred over central access in the emergent setting. Vein cutdowns, including veins otherwise ideal for later use as venous conduit, are sometimes necessary. Radial or femoral arterial lines are also often accessed for hemodynamic monitoring.²¹

8 Damage control resuscitation, a term coined in 2005, involves allowing permissive hypotension with a goal of a palpable radial pulse (in patients without head injury).²² It also includes limiting crystalloid infusion and an early institution of massive transfusion protocol with higher rates of plasma and platelets to prevent/reverse coagulopathy.²³

General Intraoperative Considerations and Pearls

Often the theory of “damage control” and “life over limb” takes precedence in the chaotic trauma bay and operating room. But there are basic tenants to follow when thinking beyond: control hemorrhage, restore blood flow, and prevent further injury.

1. Prep widely, considering any possible procedure including the need to obtain vascular conduit (i.e., saphenous vein). With leg injuries, prep circumferentially, and include the shoulders, chest, and abdomen. With chest or abdominal injuries, prep both groins. With neck or upper extremity wounds, prep the chest.
2. Patients should receive preoperative antibiotics, based on local guidelines.
3. Longitudinal incisions that are parallel with neurovascular bundles should be used for the widest exposure and best control. They may need to be S shaped over joint spaces. Minimization of the devitalization of intervening tissues can improve arterial and venous collateral flow, and provide coverage after repair.

4. Proximal and distal control for any vascular injury is critical. This may be obtained with a digit, vessel loop, vascular clamps, or a Foley or Fogarty balloon. Consider remote proximal control when hematomas or open blast wounds impede visualization. Shunts should also be considered to decrease ischemic time when orthopedic stabilization or other life-saving procedures must occur first. Nonbleeding wounds should not be disturbed including removing debris or foreign objects until surgical control is possible. Temporary application of a lower extremity tourniquet may be helpful with multiple wounds or before control is attained. An inappropriately applied tourniquet inflated to venous pressure can increase exsanguinating hemorrhage; it may need to be increased to stop bleeding that may recommence once resuscitation is underway and systemic blood pressure increases.
5. Injury may require orthopedic surgeons to perform fracture reduction and limb stabilization prior to vascular, nerve, or soft tissue repair. This will often improve vessel spasm and vascular examination should be repeated.
6. Systemic heparin use is individualized and depends on multiple factors: preoperative blood loss, hemodynamic stability, amount of ongoing bleeding, presence of brain injury, and status of patient with regard to acidosis, hypothermia, and coagulopathy. Local administration of heparin and papaverine can also be used in the wound and as vessel flushes. In general, systemic heparin is not indicated in young patients with good vascular repairs who otherwise have healthy vessels (no chronic atherosclerotic disease).
7. Exposure of the injury and vessels depends on the location, and can involve aggressive debridement of devitalized tissue for adequate visualization and postoperative healing ([Table 27-1](#)).

Table 27-1 Exposures in Vascular Trauma Surgery

Vessel Injured	Exposure/Maneuver
Right subclavian artery Ascending aorta Innominate artery	Median sternotomy
Left subclavian artery Descending thoracic aorta	Left thoracotomy
Paravisceral, infrarenal aorta Left renal artery Left iliac artery	Left colon mobilization
Inferior vena cava Right renal artery Right iliac artery	Right colon mobilization, extended Kocher maneuver (duodenal mobilization)

8. Inflow and outflow must be assessed before beginning an anastomosis; thrombectomy with a Fogarty embolectomy catheter may be required.
9. Ensure bleeding has stopped, reassess hemodynamic status of patient, and complete repairs with correct prioritization (including artery before veins in most situations).
10. Decision is made on which tension free repair to execute ([Table 27-2](#)).
11. Appropriate conduit is obtained, if applicable. Reversed greater saphenous vein of the uninvolved leg is an ideal conduit.
12. Repair is performed with nonabsorbable, monofilament running suture in most cases, and hemostasis is obtained. Hemostatic agents can be parenteral (e.g., tranexamic acid for hyperfibrinolysis;) or topical ([Table 27-3](#)).
13. Repair should be assessed in the operating room with Doppler and possible arteriogram.
14. Muscle and/or soft tissue coverage over repairs should be utilized when feasible to decrease contamination, dessication, and disruption.
15. Compartment syndrome must be considered, and fasciotomies performed as needed.
16. Wound care, physical and occupational therapy must be robust and intensive postoperatively.

Table 27-2 Options for Treatment of Vascular Injuries

Type of Repair	Uses, Indications
Lateral repair	<25% vessel compromise
Patch angioplasty	<50% vessel compromise
End-to-end anastomosis	<2 cm defect, ends mobilized, spatulated (smaller vessels)
Interposition graft	>2 cm defect, reversed vein or PTFE (if would be tension)
Extra-anatomic bypass	Extensive defect, multiple level injury, contamination

MANAGEMENT OF SPECIFIC INJURY PATTERNS—EXTREMITY

For all extremity trauma, management algorithms follow as listed in a previous section starting with advanced trauma life support protocols, controlling hemorrhage, alleviating ischemia, and limb stabilization to minimize future disability, in that order.²⁴ Injuries with hard signs of vascular injury will be taken immediately to the operating room for open and/or endoluminal diagnosis and interventions once life supporting measures allow, without further workup. Presence of hard signs has an almost 100% sensitivity of existing vascular injury. Whereas soft signs, with only a 5% specificity for detecting arterial injuries, allow time for further workup, imaging, and decisions into operative, endovascular, or nonsurgical observation categories.²⁵

Generally, the sequence should be stabilization of the extremity with or without the use of a temporary vascular shunt, revascularization, and then as patient condition allows debridement, nerve repair, and soft tissue coverage. Temporary vascular shunts have been shown in many military studies as a successful adjunct in damage control situations with reduced rate of amputations (Figs. 27-4 and 27-5).

An additional issue relevant to all extremity trauma is whether to repair venous injuries. It depends on resources, comorbidities, other injuries, and of course, stability of patient. Ligation of veins is better tolerated in upper extremities than lower. When harvesting the greater saphenous vein for conduit, it should be from the uninjured leg when feasible to allow full venous drainage of injured leg (Fig. 27-6).

Table 27-3 Topical Hemostatic Agents

	Indications	Agent Potency/Mechanism	Uses	Examples
Level I (mechanical hemostat)	Min or mild bleeding, localized	Contact activation ± platelet aggregation	Capillary, arteriolar ooze	Gelfoam, procine gelatin, bovine collagen, surgical, nu-knit, Arista
Level II (Thrombin)	Min or mild bleeding diffuse	Converts fibrinogen to fibrin activated platelet aggregation Contact activation + fibrinogen converted to fibrin	Capillary, ooze Capillary, arteriolar ooze, spurting	Bovine thrombin, recombinant thrombin Collagen or gelatin + thrombin; Floseal, Surgiflo
Level III (fibrin sealant, combination hemostat)	Mild bleeding diffuse; moderate bleeding	Fibrin sealant, replicates final stage of clotting cascade Synthetic sealant, covalently and mechanically bond Other	Capillary, arteriolar ooze High pressure sealing	Thrombin + fibrinogen ± fibrinolysis inhibitor; Tisseel, Evicel PEG polymer; coseal Biogluc

Adapted from Shander A, Kaplan LJ, Harris MT, et al. Topical hemostatic therapy in surgery: bridging the knowledge and practice gap. *J Am Coll Surg*. 2014;219(3):570–579.

Figure 27-5. Operative photograph showing temporary vascular shunts placed as a damage control maneuver in the proximal popliteal artery and vein of the left lower extremity. The shunts had been secured with silk suture ties, and both were patent with Doppler flow several hours after the injury. Note also the operative approach to the left above-knee popliteal fossa that includes a proximal Wietlaner retractor and a distal Henly popliteal retractor, and short handheld Wylie renal vein retractor.

9 A critical issue in all extremity trauma management is evaluation of compartment syndrome. Elevated fascial compartment pressures can be due to reperfusion, hematoma, swelling from crush injury or major fractures. There must be a low threshold for performing fasciotomy, based on clinical suspicion of present or pending compartment syndrome. Diagnosis is based on a high index of suspicion suggested by any of the following: >4 to 6 hours of ischemia, crush injuries, combined arterial and venous injuries, vessel ligation, tense compartments, pain out of proportion and on passive motion, poikilothermy, pallor, paralysis, paresthesia, and finally, pulselessness. Compartment pressures can be measured as an adjunctive aid in diagnosis. A commonly used cutoff is 30 mm Hg, but normal pressures with a concerning examination should not deter from pursuing treatment with fasciotomy.

Postoperative considerations include starting aspirin as soon as possible, DVT prophylaxis, elevation of the injured extremity, 24 hour of antibiotics, and starting rehabilitation as soon as appropriate in patient's condition. Systemic heparinization is usually not required postoperatively, and DVT prophylaxis and/or antiplatelet agents can suffice.

Figure 27-6. Operative photograph showing interposition vein graft repair of the left proximal popliteal artery and vein. The interposition grafts were performed after removal of the temporary vascular shunts and consisted of greater saphenous vein from the right (contralateral) lower extremity.

Upper Extremity

Anatomically, the axillary artery is defined proximally by the lateral margin of the first rib and distally by the lateral edge of the teres major muscle. The artery is protected proximally within the shoulder from penetrating injury, but susceptible to forceful blunt trauma due to its fixation. It is difficult to expose proximally due to the artery's location under the clavicle and may require either infra- and supraclavicular incisions to gain control, or a more proximal intrathoracic or mediastinal approach of the subclavian artery. The mid- and distal axillary artery can be approached through a traditional infraclavicular incision. The complications with more distal exposure are due to increasing branches and associated nerves leading to the shoulder and arm. Employing endovascular techniques for temporary balloon occlusion or placement of stent grafts may be advantageous in either of these locations.²⁶

The axillary artery becomes the brachial artery, which runs in the anterior compartment of the arm with the median nerve. Two veins accompany, and often cross over, the artery – the basilic and brachial veins. Exposure of the brachial artery is simple compared to the axillary, in the medial groove between the biceps and triceps muscles. The brachial artery is most often injured during penetrating trauma, but should be considered with any humerus fracture, especially posterior or lateral fractures. The brachial artery's main proximal branch, the profunda brachii, can provide significant perfusion to the distal upper extremity if it remains intact.

The radial artery is a terminal branch of the brachial just distal to the elbow and travels in the anterior compartment to become the deep palmar arch. The ulnar artery is the larger terminal branch of the brachial artery and runs to the wrist to form the superficial palmar arch and joins the deep arch. If temporary control of bleeding is needed, a blood pressure cuff can be used as a tourniquet; clamps should never be placed blindly into a bleeding wound due to the high risk of nerve injury. Evaluation should include the previously described neurovascular examination with addition of the Allen test to determine patency of the palmar arch. Some believe a single vessel injury with no ischemic changes can be ligated if the palmar arch is intact. If both forearm arteries are injured, the usually dominant ulnar repair is preferred, primarily or with vein from ipsilateral arm or dorsal foot vein. There is limited to no role for acute management of traumatic forearm injuries by endovascular means.

Lower Extremity

Femoral trauma constitutes 20% of all traumatic arterial injuries. Supracondylar femur and tibial plateau fractures are associated with distal superficial femoral artery and popliteal artery injuries. Acute ligation of the femoral artery leads to 50% amputation rate.²⁷ Previously stated management principles should be followed for the lower extremity as well with some site-specific caveats. Some situations may require control of hemorrhage via an assistant's digit prepped into field, a temporary balloon catheter or tourniquet, or exposure of the distal external iliac artery in the preperitoneal space with compression against iliac fossa for femoral triangle injuries. Incision should be longitudinal just distal to the inguinal ligament. Primary repair or interposition grafts are the mainstay of therapy. Although vein conduit is always preferred, prosthetic graft can be used when necessary, in larger vessels with good muscle coverage. Heavy contamination (such as a bowel injury) may make an extra-anatomic bypass necessary, at least temporarily. Endovascular techniques can be employed in certain circumstances in the femoral and popliteal region including coiling arteriovenous fistulae or pseudoaneurysms, stenting pseudoaneurysms or transections that can be crossed.

Popliteal trauma is classically due to posterior knee dislocation. Historically, amputation rates were 20% for both penetrating and blunt popliteal injuries.²⁸ While failure to repair a popliteal occlusion results in over 60% amputation rate. Incision should be medial, employ the use of a bump under the slightly flexed leg, and utilize deep self-retaining retractors (Figs. 27-5 and 27-6). Repair is primary, interposition graft, or with a stent. Primary repair should be attempted only if defect is <1 cm. Completion angiography is recommended in most situations.

Reportedly, a single terminal vessel can be ligated in the lower extremity in a patient with no signs of ischemia and no peripheral vascular disease. Whenever possible, preserving three artery perfusion to the foot is preferred. When all three arteries are damaged, repair should focus on the posterior tibial via a medial incision or anterior tibial via a lateral incision.

MANAGEMENT OF SPECIFIC INJURY PATTERNS – CERVICAL

The carotid artery travels in the anterior cervical triangle of the neck, specifically the carotid triangle bordered by the sternocleidomastoid muscle, the superior belly of the omohyoid muscle, and the posterior belly of the digastric muscle. Of course, besides hemorrhage from carotid artery, jugular veins and branches, injury to nerves (vagus, hypoglossal), trachea, and esophagus must also be considered. The vertebral artery, which supplies blood to the posterior brain, travels first in the transverse foramina of the cervical vertebrae and then in the vertebral canal.

10 When discussing neck trauma, there are three regions classically used to describe anatomic location. Zone I is below the cricoid cartilage, zone II is between the cricoid cartilage, and the angle of the mandible, whereas zone III is above the angle of the mandible. The carotid and vertebral arteries are at risk in all three zones.²⁹

Neck trauma is also divided into penetrating and blunt injuries. Zone II of the neck is the most commonly injured region at 47% of penetrating neck injuries. The most commonly injured structure within the neck is blood vessel, with a 20% incidence of major vascular injury in penetrating neck trauma. These injuries lead to a 7% to 27% stroke rate and 7% to 50% mortality rate; 80% of deaths due to penetrating neck injuries are attributed to stroke.³⁰ Evaluation of these injuries used to include a mantra “operate if penetrated the platysma” but this is no longer the rule as it has been shown to lead to a 50% to 90% negative exploration rate. Currently, CTA is used whenever the patient is deemed stable enough to travel to CT scan. The CTA should include the neck and head, with extension through the aortic arch if a zone I injury is suspected. CTA has a 90% sensitivity and 100% specificity rate for vascular injuries that require treatment.³¹

As stated, treatment of injuries with hard signs in zone II is emergent operative exploration. This can be undertaken often via a cervical incision. Stab wounds can often be repaired primarily or with a patch, while ballistic injuries typically require segmental resection with interposition graft. Greater saphenous vein should be used as conduit whenever possible. Internal jugular can be ligated in an emergent setting, but otherwise should be repaired, especially if injury is bilateral. External jugular and facial veins can be ligated without significant consequence, as can the external carotid artery. Internal carotid artery should be repaired as there is a high mortality with ligation (45%).³⁰ Heparinization with or without shunting is employed during these repairs unless major contraindications exist in the multi-injured trauma patient.

Zone I and III injuries are much more difficult to expose using an open approach. Thus, they are often managed with open surgery, endovascular intervention, or a hybrid combined approach depending on location, comorbid conditions, other injuries, stability of patient, and availability of resources. Endovascular approaches have become particularly appealing for injuries at the thoracic outlet and skull base, which are especially difficult to access during open surgery.

Zone I injuries with hard signs of vascular injury typically involve the great vessels. These need to be managed with either an endovascular approach (cover stents and endografts) or open clamp for proximal control via median sternotomy, high anterior thoracotomy, or clavicular resection. Common carotid can be controlled via a sternotomy, and portends a lower risk of stroke than clamping the internal carotid due to collateral flow via external carotid and the circle of Willis.

Open control of zone III injuries can require subluxation of the mandible (jaw dislocation), mandibulotomy, and other morbid exposures so endoluminal control is appealing in this region as well. A temporary occlusive balloon while exposure and hemostasis is obtained, coil embolization, and a covered stent placement over the injury are strategies that have been used. Covered stent have been described in the treatment of traumatic carotid injuries. The results are inconsistent and based on small studies. One study placed stents in 10 patients with carotid dissections, neurologic changes and contraindication for or failure of anticoagulation with good overall results. Whereas a contemporary study of 23 patients who underwent carotid stent placement for traumatic pseudoaneurysm documented a 21% complication rate and 45% occlusion rate, both higher rates than the patients treated with antithrombotic therapy alone.^{29,32}

Vertebral artery injuries are less common, and more difficult to expose and control operatively, than carotid artery injuries. Vertebral artery injuries are most often associated with cervical spine transverse process fractures, subluxations, or penetrating injuries to the back of the neck. Only medical management is needed if the injury is not bleeding. Endovascular means of embolization has been employed for pseudoaneurysms and intimal disruption (and is technically a better option whenever possible), if the vessel is not already thrombosed. Open access to the vertebral artery may be necessary to control bleeding if endovascular approach cannot be used for any reason (not available or not enough time, etc.). This involves an exposure similar to that for the carotid artery, and after the sternocleidomastoid and anterior scalene muscles are mobilized, vertebral artery can be isolated and ligated. In this procedure, care must be taken to avoid injury to the phrenic nerve and thoracic duct. To obtain proximal and distal control of a more distal vertebral artery injury may require employing similar techniques as with a zone III carotid injury. The expected stroke rate of ligation of the vertebral artery in the spine literature is 0% to 8%. However, whenever possible, medical therapy with antithrombotics is still the primary treatment modality.

Blunt vascular trauma to the neck is usually considered as blunt cerebrovascular injury (BCVI) and encompasses both carotid and vertebral injuries (often discussed as one). BCVI represents <1% of admissions for blunt trauma, but the impact is great when considering these injuries lead to a 12% to 58% stroke rate and 31% to 59% mortality rate when untreated.³³ The goal of management is thrombosis prevention, therefore treatment with antithrombotic therapy is recommended. Two such examples reported a reduction in stroke rate from 64% to 6.8%, and 46% to 0% in blunt carotid injury patients treated with any antithrombotic agent.³⁴ However, the optimal drug(s) and duration for each injury grade has not yet been determined by prospective data. This could include aspirin, clopidogrel, anticoagulation, for a set time versus life long. Retrospective data have shown equivalence in injury outcomes with antiplatelet and anticoagulation treatment regimens.

MANAGEMENT OF SPECIFIC INJURY PATTERNS – TORSO

11 Control of bleeding from vascular disruption within the torso is not readily amenable to control with direct pressure and is therefore referred to as noncompressible torso hemorrhage (NCTH). Civilian studies demonstrating that NCTH accounts for 60% to 70% of mortality following otherwise survivable injuries clearly emphasize the lethality of this injury pattern. Hemorrhage is also a significant problem in the wartime setting, accounting for up to 60% of deaths in potentially survivable injury scenario. The distinction between compressible extremity hemorrhage and NCTH is notable. There has been a demonstrable reduction in mortality from extremity injury with a better understanding of its epidemiology and the need to rapidly control hemorrhage with tourniquets and/or topical hemostatic agents. To date, there has been no such reduction in mortality in the setting of NCTH.³⁵ Vascular disruption with bleeding can arise from an array of anatomic sites:

- Large axial vessels
- Solid organ injuries
- Pulmonary parenchymal injuries
- Complex pelvic fractures

As such, the definition of NCTH begins with the presence of vascular disruption from one or more of four anatomic categories listed above.

Management of Torso Hemorrhage

12 Despite advances in surgical understanding, technique, and technology, one fundamental tenet remains: Proximal and distal control is essential when managing suspected vascular injury. The majority of patients with these types of injuries qualify for management in a damage-control fashion and the appropriate surgical maneuvers depend primarily on the location of hemorrhage within the torso.

Thoracic Cavity

Vascular trauma to the aortic arch and its major branch vessels is rare and the majority of patients present in shock, requiring immediate surgical intervention in the form of tube thoracostomy, resuscitative thoracotomy (RT), or median sternotomy. Aortic arch injuries are often associated with multiple other vascular injuries, including vena cava, innominate vein, and pulmonary artery injuries and a median sternotomy is the operative exposure of choice. Sternotomy followed by division of the innominate vein allows the pericardium to be opened for release of any associated cardiac tamponade. Exposure of aortic branches can be facilitated by extending the sternotomy incision proximally as a supraclavicular incision with division of the sternocleidomastoid muscle.

For hemorrhage control within the thoracic cavity, access to the ipsilateral side is best via an anterolateral thoracotomy, through the fourth interspace, with the patient in the supine position, tilted up on a roll. This approach also allows extension of this incision across the sternum into the right hemithorax or the clam-shell incision, permitting access to either of the other two compartments in the chest (mediastinum and contralateral thoracic cavity) if required. It is important that a surgeon performing this maneuver must also have the ability to concomitantly explore the abdomen, so this must be included when preparing the surgical field.

Once within the chest, hemorrhage control is the priority. Pulmonary bleeding can be controlled using several techniques, depending on location. Injury to the periphery of the lung can be stapled off in a nonanatomic fashion using a linear stapler. If hemorrhage from the lung is from the deeper hilar structures, the lung itself (after mobilization) can be compressed or even twisted on itself to occlude the hilar vessel. In cases where the injury significantly compromises a patient's pulmonary reserve, extracorporeal life support (ECLS) may also be a useful adjunct.

Abdominal Cavity

The abdomen should be opened through a midline incision from the xiphoid process to the pubic symphysis to permit access to all 4 quadrants. Initial packing remains the best method of initial hemostasis, allowing for the resuscitation to restore the circulating volume. An additional useful adjunct for patients in extremis is resuscitative aortic occlusion of the aorta at the diaphragmatic hiatus. The next key steps are sequential evaluation of the abdomen, decisions regarding local control of hemorrhage and contamination and the type of reconstruction required for any large vessel injury ([Fig. 27-7](#)).

Hemorrhage from the solid organs of the abdomen is managed differently, depending on the organ in question. Exposure and removal of the spleen is fairly straightforward and well tolerated by the patient, and thus splenectomy is the favored maneuver for the hemorrhaging spleen. By contrast, hemorrhage from the liver necessitates packing to control venous bleeding in most instances. Control of the porta hepatis at the gastrohepatic ligament and application of the Pringle maneuver is often used as an adjunct to liver packing to control inflow to the organ. Depending on the nature of the wound and the location of the hepatic bleeding, the liver can be mobilized by dividing the coronary and triangular ligaments and allowing the left and right lobes to be drawn or compressed together.

Retroperitoneum

Posterior to the peritoneal sac lies the retroperitoneum, which can be divided into four zones. Zone I is centrally located and contains the aorta and IVC. Hemorrhage often manifests as a hematoma and should always be explored in this zone. Management of such injuries should adhere to standard principles of proximal and distal control of the vessel. The aorta can be widely exposed through a left medial visceral rotation – also referred to as the Mattox maneuver by mobilizing the left colon and kidney. The IVC can be explored through a right visceral rotation – also referred to as the Cattell–Braasch maneuver – by mobilizing the large and small bowel fully to the root of the mesentery.

Approaching large-vein injuries in the abdomen is often more challenging than controlling and repairing arterial hemorrhage. Like bleeding from large arteries, one must be prepared with multiple suction devices and a good retraction device, and be sure that the anesthesia team is prepared with warmed rapid transfusion devices. Because large veins often do not tolerate clamps in the setting of trauma and hematoma, direct pressure should be applied with sponge-sticks or the smaller Kittner dissector sponges. These devices substitute for manual pressure and allow one to create more visibility in the operative field.

Zone II is perirenal in location and generally should be managed conservatively in blunt trauma, provided there is no expansion and the patient is hemodynamically stable. Penetrating trauma requires a different approach, with an emphasis on exploration and repair of the kidney if possible, or nephrectomy. If there is concern of injury to or violation of the collecting system, drains should be left in the perinephric or retroperitoneal space.

Zone III originates from within the pelvis, although these injuries can be extensive, tracking all the way up to the supracolic compartment. Pelvic hematomas are best managed conservatively in blunt trauma, and opening them should be avoided. Further management options are outlined below. In penetrating, vascular control is vital, especially if a direct vessel injury is suspected, and may require mobilization of the terminal aorta.

Operative management of bleeding from the portal-retrohepatic zone (sometimes referred to as zone IV) is fraught with difficulty. Control of bleeding from the retrohepatic vena cava is especially challenging and is associated with high mortality. Contained hematomas should be left undisturbed, and expanding lesions should be packed in the first instance.

Pelvis

The pelvis is a complex compartment containing several unique anatomic structures typically managed in the elective setting by specialists from a range of disciplines (e.g., urology, orthopedic surgery, vascular surgery, and general/colorectal surgery). Operative exposure of the pelvic space can be achieved through either a transperitoneal approach at the time of laparotomy or with an extraperitoneal approach, which can be accomplished through a midline or a Pfannenstiel incision. The former is the quicker approach, enabling access to both the abdomen and the pelvis and permitting access to the aorta and distal vascular along with the hollow viscera within that region. The extraperitoneal approach allows access to the external iliac vasculature for suprainguinal arterial control and for packing of the preperitoneal space. The latter is a useful adjunct to managing venous bleeding in complex pelvic fractures once bony stabilization has been achieved. Arterial bleeding from the pelvis is most commonly managed with endovascular techniques such as coil embolization in cases of complex pelvic fracture. In rare instances of pelvic fracture or open fragmentation or gunshot wounds to the pelvis, ligation of the internal iliac artery is necessary as a hemorrhage-control maneuver.

A proportion of patients with NCTH present with circulatory collapse, either profoundly hypotensive or in cardiac arrest. Management of patients presenting in such a fashion has been extensively studied.

The current civilian standard of care is to perform a RT, which permits the following maneuvers:

- Release of cardiac tamponade
- Management of thoracic bleeding
- Control of massive air-leaks
- Internal cardiac massage
- Thoracic aortic occlusion

The latter maneuver is undoubtedly the most practiced, as aortic control theoretically enhances cerebral and myocardial perfusion. Aortic occlusion can also be achieved by endovascular balloon occlusion, as demonstrated by the use of percutaneous devices used to control the neck of abdominal aortic aneurysms during endovascular repair.³⁶ This technique enables the physiologic benefit to be realized without the additional burden of entering a body cavity. Such a technique has been used in trauma as early as the Korean War and since.³⁷ With recent improvements in endovascular devices and resuscitation in general, there is a renewed interest in this approach, which has been termed resuscitative endovascular balloon occlusion of the aorta (REBOA) (Fig. 27-8).^{38,39}

Figure 27-8. Fluoroscopic image of a compliant balloon inflated in the descending thoracic aorta as part of the maneuver referred to as resuscitative endovascular balloon occlusion of the aorta or REBOA. This endovascular maneuver was accomplished through a percutaneous sheath in the right femoral artery and can be accomplished in certain scenarios instead of an open resuscitative thoracotomy with aortic clamping to restore proximal central aortic pressure and mitigate distal bleeding. (From Scott DJ, Eliason JL, Villamaria C, et al. A novel fluoroscopy-free, resuscitative endovascular aortic balloon occlusion system in a model of hemorrhagic shock. *J Trauma Acute Care Surg* 2013;75:122–128.)

CONCLUSION

Vascular trauma remains a leading cause of mortality and morbidity following civilian and military injuries. A large volume of military supported epidemiologic and translational research stemming from the wars in Afghanistan and Iraq has advanced the understanding and treatment of this injury pattern. Evidence suggests that the commonality of vascular trauma is increasing at a time during which familiarity with its management (open and endovascular) is on the decline. Supported by an understanding of modern epidemiologic patterns of injury, including mechanisms and specific scenarios, and knowledge of the range of options available to examine and image patients, providers will be able to effectively diagnose or exclude the presence of vascular trauma. This foundational understanding will also aid providers in their approach to resuscitating severely injured patients and knowing when to intervene and when not to intervene. The operative management of vascular trauma has changed with the growth of endovascular approaches to hemorrhage control and resuscitation as well as the specific treatment of several injury patterns. Still, many of the original principles underpinning the safe and effective management of vascular injury – from damage control to definitive treatment – find themselves in knowledge of traditional open operative exposure, with control and repair of the vessels (Fig. 27-7). Regardless of experience and training level, the foundational principles provided in this chapter will support one's attempts to improve his or her effectiveness in managing what is arguably

the most challenging injury pattern following significant trauma.

Chapter 28

The Principles of Orthopedic Surgery for Trauma

Raymond Malcolm Smith

Key Points

- 1 Establishing bony stability significantly reduces local bleeding.
 - 2 Major pelvic fractures occur in recognizable patterns that predict other injuries.
 - 3 Obtaining bony stability can significantly reduce pelvic bleeding and is an essential part of their initial care.
 - 4 Early stabilization of major fractures in polytrauma patients facilitates other care and saves lives.
 - 5 Early radical management of open fractures with adequate debridement, bony stabilization, and specifically early healthy soft tissue cover significantly reduces the risk of infection and decreases morbidity.
 - 6 Establishing reliable bony stability is the key for local soft tissue healing.
 - 7 The principles of accurate reduction, stable fixation, preservation of a healthy soft tissue envelope, and early rehabilitation with joint and patient mobility are the keys to general fracture management.
-

INTRODUCTION – AIMS AND PRIORITIES IN ORTHOPEDIC TRAUMA CARE

In recent years, the subspecialty of Orthopedic traumatology has become well established dealing with not only more routine fractures but also the more complex problems presented by very severe localized high-energy injury and combination multisystem polytrauma. In critical multisystem injury, it is very important to correctly manage the orthopedic injuries which must not be underestimated. Their management has a critical role in ensuring survival of the patient and ensuring practical overall clinical management. In severe local injury, useful limb salvage needs critically appropriate orthopedic management often combined with plastic surgeons to manage the severe soft tissue injury. Beyond this, in the vast majority of less severely injured patients the orthopedic surgeon's care should limit the medium- and long-term disability caused by fractures and severe peripheral soft tissue injuries. This general point of view is illustrated in [Table 28-1](#). It is useful to consider the role of the orthopedic surgeon in this regard.

ORTHOPEDIC TRAUMA SURGERY TO SAVE LIFE

Many orthopedic injuries present as part of severe multisystem trauma cases and as such are a major part of the trauma burden and the threat to life. This threat comes from hemorrhage (from individual or multiple injury sites), the general effect of multiple major skeletal injuries, specific early associated injuries or complications such as vascular injury and compartment syndrome or later complications such as issues related to infection, immobility, and thromboembolic disease.¹

Hemorrhage

1 The most immediate and absolute need for surgery in trauma is the control of bleeding. For the orthopedic traumatologist this takes two important forms, first a massive general bleeding insult associated with multiple high-energy fractures and second that associated with a specific major injury, most typically to the pelvis. Bleeding from multiple fractures is common and often underestimated. In general good transfusion protocols and early fracture management controls the situation. Bleeding from fractures will invariably slow and usually stop spontaneously when the fracture is reduced, stabilized, and the compartment tension restored. However, it is very easy to underestimate the collective blood

loss from multiple injuries and get too far behind in resuscitation. Aggressive transfusion protocols with appropriate attention to replacing volume and clotting factors with early use of blood with plasma and platelets are essential but emergency orthopedic intervention with provision of skeletal stabilization for early hemorrhage control is equally important.² This may involve wound debridement and hemostasis in the complex open injury or early long-bone stabilization in multiple closed fractures. Occasionally, temporary external fixation may be required to provide rapid skeletal stabilization when the more extensive surgery required for definitive stabilization would be inappropriate.

The Bleeding Pelvis

2 Put simply, patients with major pelvic ring injuries bleed to death. Often presenting after a high-energy injury, the pelvis as the source major hemorrhage may be obvious with massive local swelling and clear instability. At presentation, a primary plain pelvic x-ray remains the best way to quickly understand the fracture. It will allow immediate assessment of the fracture pattern, energy involved, degree of displacement and lead to an estimate of the risk of local bleeding and presence of local or distal associated injuries.⁴⁻⁸ Today many patients have a binder applied in the field for transport. This is a very effective way to initially control pelvic volume and tamponade bleeding but may reduce the deformity and lead to the initial x-ray underestimating the degree of injury.

Pelvic fractures can be classified by two major systems. Young and Burgess^{4,5} (Fig. 28-1) presented a classification system based on the implied direction of the initial force. They defined injuries essentially as anterior-posterior compression (APC), lateral compression (LC), and vertical shear (VS) injuries. This allows an assessment of the direction of the force applied, the resultant instability and can predict mortality, transfusion requirements, and associated injuries. It remains very useful in this regard, for example, a severe LC fracture on the left is likely to be seen after a high-energy motor vehicle crash (MVC) in which there was a major intrusion into the car on the side of injury. It is therefore likely to be associated with a major head injury and bleeding mainly from elsewhere; specifically, the associated ipsilateral chest and abdominal injury. A major AP injury will classically come from a motorcycle crash and will often produce major bleeding in the pelvis itself. The Tile (after Penall)^{9,10} (Fig. 28-1) system considers the injury with regard to the resultant instability and has now been adopted by the AO Foundation (AO) and Orthopedic Trauma Association (OTA). An “A”-type fracture has a stable pelvic ring and essentially includes more minor avulsion fractures and undisplaced mechanically stable pelvic ring injuries (includes APC I & LC I). “B”-type injuries are rotationally unstable but vertically stable with an intact posterior soft tissue hinge providing some stability (corresponding to APC II or LC II/III injuries) while “C”-type injuries are both rotationally and vertically unstable, implying that the posterior hinge is torn (corresponding to APC III and VS injuries). The latter carry the highest risk of bleeding and death.

Table 28-1 Why We Operate on Fractures: Priorities in Trauma Care

- Orthopedic surgery to save a life
- Orthopedic surgery to save a limb
- Orthopedic surgery to limit disability

From a surgical management perspective, A-type injuries are unlikely to be a source of major bleeding while B type and specifically C types are increasingly life-threatening. After initial assessment, primary radiology, and consideration of the response to initial resuscitation, pelvic fractures can be considered by the mechanical stability resulting from the injury and the resultant hemodynamic response (Table 28-2).

Table 28-2 Principles of Management of Major Pelvic Ring Injuries

	Mechanically Stable Pelvis	Mechanically Unstable Pelvis
Hemodynamically stable	Nonoperative	Early, planned operative stabilization of pelvic ring
Hemodynamically unstable	Likely extra-pelvic cause Angiography/embolization	Emergent provision of mechanical stability +/- Packing/angio

When considered in this way the orthopedic care follows a logical pattern. The essential contribution of the orthopedic surgeon is to assess the injury with regard to the local and associated problems it will produce and to provide pelvic mechanical stability when required. Clearly, the hemodynamically stable patient with a stable pelvic ring injury does not require major active orthopedic management although it should be noted that even the most apparently simple injury can rarely cause local bleeding and transfusion may be required.¹¹ The hemodynamically stable patient with a mechanically unstable pelvic ring injury needs early but nonemergent surgery to restore mechanical stability to the pelvis for pain relief, normal daily care, and mobilization. Hemodynamically unstable patients need emergent care to restore their physiologic stability. If the pelvis is mechanically stable, orthopedic intervention has little to offer, either there is an extrapelvic cause for the bleeding or hemostasis should be obtained by provision of appropriate clotting factors and platelets or angiographically.

3 The patient in hemorrhagic shock with a major unstable pelvic ring is a very different problem.^{11,12} Early coordinated multidisciplinary care is essential with appropriate resuscitation within an established massive transfusion protocol. It is well established that the site of hemorrhage in most bleeding major pelvic fractures is from the fractured bone surfaces and extensive soft tissue injury, and rarely from major named arteries. Fortunately, the majority of this will slow significantly or stop when skeletal stability is achieved. Unfortunately, rapid stabilization of the pelvic ring is a major expert intervention at best and is commonly not easily achievable in the acute bleeding situation. Initial reduction, stability and some local tamponade is provided by a pelvic binder. In critical cases it should not be removed without an available alternative method to provide stability. Internally rotating the hips, slightly flexing the knees and binding the legs at the thigh should also be used if possible and provides additional effective control. The provision of early pelvic fixation or a primary angiographic approach depends on local expertise and protocol. Recently, a move to emergent operative provision of skeletal stability and packing of bleeding areas has entered practice and is suggested to be a major advance.^{2,3} This considers the major bleeding pelvic injury similar to a bleeding liver and where local hemostasis can rarely be achieved and general hemorrhage control with packing for local pressure and provision of appropriate clotting factors is essential. For the severe pelvic injury, a systematic protocol with pelvic stabilization and packing at the end of an appropriate decision-making tree is essential.^{2,3} Emphasizing the importance of not getting out of control or reacting too late, “The Denver Protocol”^{2,3} begins with a patient with shock, a pelvic ring injury, and a failure to respond to 2 L of crystalloid resuscitation and 2 units of blood transfusion ([Algorithm 28-1](#)). The essential principle is early aggressive surgical management for hemorrhage control with preperitoneal packing and rapid blood and factor replacement before the patient becomes grossly coagulopathic. From the orthopedic point of view, restoring skeletal stability is a critical part of this process and close cooperation with the general traumatologist is essential.

Figure 28-1. A–C: Young and Burgess and Tile (AO-OTA) classifications of pelvic fractures (from Wiss DA. *Master Techniques in Orthopaedic Surgery: Fractures*. 3rd ed. Philadelphia, PA: Wolters Kluwer Health; 2012.)

Pelvic Packing

The procedure of packing a pelvis for hemorrhage is not complicated and well within the capabilities of most surgeons but some form of pelvic bony stability has to be achieved first to give a solid base to pack into. In the emergency situation this commonly means the application of an anterior external fixation frame although if available and possible, internal fixation has many advantages. Occasionally, emergency provision of posterior stability with emergent percutaneous sacroiliac fixation or application of a “C clamp” can be dramatically effective in restoring stability and markedly slowing bleeding. Preperitoneal packing is done through a small anterior incision just above the pubis. After separating the rectus muscles (which may be avulsed from the pubis), the cavity created by the trauma is entered, the hematoma evacuated and rapid mechanical stability obtained (often temporarily, with an immediate anterior clamp across the pubis). The cavity is then packed with as many packs required. These should be placed as far back into the true pelvis as possible. The hematoma cavity created by the injury will be obvious and it is not required or desirable to extend the dissection outside this area but it is essential to get the packs right to the back of the cavity. Assuming hemostasis is achieved, the packs are left in, often for 48 hours and under an open but sealed abdomen before they are changed or simply removed depending on the physiologic response.

Complicated Pelvic Injuries – Open Fractures or Associated Visceral Injury

The initial assessment of any patient with a pelvic fracture must include an inspection of the perineum with rectal and vaginal examination to check for complex open injuries or associated urologic injuries. Open pelvic fractures and those complicated by damage to the local viscera need specific treatment based on the wound or specific visceral damage sustained.^{13,14} While the mortality and complexity increases with the risk of contamination and infection the orthopedic principles of open fracture care remain the same. Any open fracture is considered contaminated and dealt with along the principles described below of debridement and lavage, establishment of bony stability and early, healthy soft tissue cover as required. However, in major pelvic injuries there is usually a massive trauma cavity where contamination and infection would prove fatal. Aggressive decontamination and protection of this extensive zone of injury from further contamination by diversion of the fecal stream may be essential.

Mauffrey C, Cuellar DO 3rd, Pieracci F, et al. Strategies for the management of hemorrhage following pelvic fractures and associated trauma-induced coagulopathy. *Bone Joint J* 2014;96(9):1143–1154.)

Complex urologic injuries are commonly seen with specific patterns of pelvic fracture. A significant APC injury is commonly associated with an extraperitoneal bladder rupture of the anterior bladder wall directly in line with the plane of injury. LC injuries may be associated with urethral tears as the inferior ramus cuts the male membranous urethra as it is forced across the midline by the injury. In all cases the

presence of hematuria or blood at the meatus is the pathognomonic sign of injury and necessitates appropriate investigation and joint management with the urologic service. Again from the orthopedic point of view no soft tissue reconstruction can work without an underlying stable bony skeleton to support the repair and prevent reinjury. In many situations, the best access the urologist will have is at the time of the primary bony stabilization and early urologic repair or diversion avoids many problems. While a staged urologic procedure may be required, very early combined surgery has much to recommend it.

The Orthopedic Management of Major Polytrauma

4 Major trauma is a surgical problem, and the essence of management is to take control and stay in control of the trauma and do no further iatrogenic harm. From the orthopedic point of view, this means that it is essential to gain control by stabilizing the skeleton. This understanding has developed through quite opposite phases to now consider all elements of the injury and physiologic priorities. The management protocols have focused on the changing opinions about stabilization of the femur fracture which has become the index injury in this regard. Essentially, despite the development of long-bone nailing by Kuntscher¹⁵ in the 1940s, through till the late 1980s most Western surgeons believed that seriously injured patients were “too sick to operate on” and used traction devices as the primary mode of treatment for major fractures. Concern that this was not the best mode of treatment led to the term “Horizontal Crucifixion” and several early publications^{15–17} suggesting a major advantage of early surgical stabilization of the fractures, specifically with femoral nailing. Johnson¹⁸ confirmed this effect and showed that it appeared to be greater the more severely the patient was injured and in 1989 Bone¹⁹ published his landmark paper, a prospective randomized trial of early against late femoral nailing after severe injury. Essentially he showed that there was a major advantage in early nailing and the pendulum swung to enthusiastic universal early skeletal stabilization after polytrauma. The patient was now considered “too sick not to operate on” and a management philosophy now termed “Early Total Care” developed. This practice was soon questioned, specifically in Germany where the orthopedic trauma surgeon is closely involved with intensive care and inevitably observed the combined effect of other injuries. Pape et al.²⁰ again considering the femur, looked specifically at the effect of early and late femoral nailing in severe polytrauma and showed the deleterious effect of an associated chest injury in association with femur fractures treated by early reamed nailing. While statistically the effect seemed more related to the chest injury than the nailing, this alerted the profession to the combination effect of these injuries and stimulated an outpouring of research looking at the general and immunologic effects of orthopedic procedures and specifically of reaming the femur.^{21–36} Eventually, a concept of the general effects of polytrauma and bony injury has become more widely accepted and a concept of the appropriate surgery (damage control orthopedics – DCO) for the most severely injured patients developed.

Essential Damage Control Surgery in Orthopedics

Damage control in orthopedics means taking control of the musculoskeletal elements of the injury without creating an increased trauma load due to increased surgical bleeding or a lengthy surgery associated with definitive care of complex fractures (Fig. 28-2). After essential hemorrhage and wound management this involves restoring major skeletal stability usually by the rapid application of external fixators. The basic physiologic parameters are then normalized in a critical care environment unit and definitive stabilization is delayed until the peritraumatic immunologic storm has settled.^{25,26,28,29} The most critical element is the speed and accuracy of the initial surgery as the critical injured patient cannot tolerate a long orthopedic procedure. However, it cannot be underemphasized how important the principle of establishing early skeletal stability remains; this was the major lesson of the early Johnson/Bone papers^{18,19} and has never been disputed, the issue is not if, but how this is obtained. In situations where the patient can tolerate it, there are major advantages in early definitive skeletal stabilization. The question is, how do we identify which patients are too sick and for what? Long orthopedic procedures and protracted bleeding must be avoided and nailing the femur seems to be particularly excessively stimulating. A variety of parameters have been investigated to help with this decision.²⁵ Measurement of interleukin-6 (IL6)²⁴ has not achieved its initial promise and today a spectrum of parameters considering the patient's general condition are commonly used.³⁰ This essentially means close communication and protocol agreement with the anesthetic/general trauma team but is primarily a surgical decision as the anesthetic team is less likely to be trauma specialized. Basic parameters to be considered include the hemoglobin/hematocrit, ventilation parameters, platelet

count and coagulation studies, patient temperature and a measure of acidosis, usually the lactate level. The latter has been widely used as measure of resuscitation and as the primary decision-making parameter by many orthopedic surgeons. Initially, a level of 2.5 mmol/L was considered the value above which surgery should not proceed but the more recent work from Vallier et al.³⁰ has suggested a lactate level of 4 mmol/L is a safe cutoff. However, surgical decision making in critical illness does not occur in isolation and improvements in early resuscitation and critical care management mean constant reappraisal and probably another future swing in the pendulum (Table 28-3).

Figure 28-2. Early damage control of extensive limb injuries with external fixation.

Table 28-3 Essential Priorities in Orthopedic Damage Control

Principle	Example
Surgical hemorrhage control	Direct control, pelvic packing, long-bone stabilization
Cavity decompression	Compartment syndrome
Debridement/decontamination	Major open wounds/fractures
Revascularization	Repair vascular injury to revascularize the limb if patient is well enough, if not amputate
Fracture stabilization	Usually rapid external fixation of major long-bone injury/pelvis
Critical care	Ongoing resuscitation, rewarming, and factor replacement prior to delayed secondary surgery
Delay reconstructive surgery	Conversion of external fixation to nails, definitive joint reconstruction

Special Polytrauma Situations – Head Injury

The orthopedic priorities change in specific scenarios the most obvious being the associated head injury. When the brain is at risk the primary aim is to maintain cerebral oxygenation and cerebral perfusion pressure (CPP); accordingly, orthopedic procedures especially those that would lead to bleeding, swings in blood pressure and thus episodes of reduced CPP should be avoided. However, there are definite advantages in having a stable skeleton and being able to sit the patient up which will help oxygenation and general critical care such that after appropriate discussions bony stabilization at the right time is strongly indicated.^{37,38}

Special Polytrauma Situations – Chest Injury and Femur Fractures

The effect of the chest injury is discussed above. It was emphasized by Pape and Tscherne and innumerable papers that followed.²⁰ While multiple studies have shown the advantages of early skeletal stabilization there is no doubt that the lungs are vulnerable to further insults after injury, and that the acute lung injury can be worsened by fat embolization especially during femoral canal instrumentation. While improvements in reamer design reduce canal pressurization and smaller nails have been

advocated, delaying definitive nailing for 4 to 5 days after initial external fixation in the most critical patient is probably the standard of care. The effect seems to be dose dependent such that the patient with bilateral femur fractures is at a significantly increased risk and some surgeons avoid bilateral femoral nailing at the same time even in healthy patients.³⁹⁻⁴²

Specific Orthopedic Scenarios

Major Wounds

5 The ongoing septic effect of major wounds can be critical. In the first instance, debridement of necrotic tissue from the trauma is essential and commonly inadequately done at the initial surgery. Wounds will never stabilize until adequately debrided and when associated with fractures will not heal until bony stability has been established. The management of complex open fractures is described below; in polytrauma cases the principles remain the same but the ability to obtain early soft tissue cover is compromised by the patient’s general situation.

Table 28-4 Open Fracture Surgical Principles

Debridement to healthy margins and profuse lavage/ decontamination
Bony stabilization
Early, healthy soft tissue cover

ORTHOPEDIC TRAUMA SURGERY TO SAVE LIMBS

Open Fracture Principles

Open fractures can range from simple to destructive injuries but in all the important feature is that the fracture hematoma communicates with the outside environment and the fracture is thus potentially contaminated. As such, their specific management revolves around limiting the chance of this contamination converting to established infection. General measures include the provision of tetanus cover, early broad spectrum antibiotics, early splintage, wound dressing, and specific surgical management. The latter is designed to reduce the degree of contamination, to remove necrotic or threatened tissue likely to become infected and to protect the limb by making it unlikely to develop further infection due to an unstable open wound (Tables 28-4 and 28-5).

Appropriate and adequate open fracture debridement is one of the most difficult surgical procedures, it should not be relegated to inexperienced staff and if possible not attempted at night unless the limb is very seriously threatened. The whole zone of injury must be assessed and all dead and dying tissue removed, only nerve and vessel must be preserved and poor muscle specifically removed. Any free bone or fragments attached by flimsy soft tissue should also be removed and the resulting defect dealt with accordingly, although only rarely is a significant defect produced. Wound extensions need to be placed with specific consideration for the later closure and must not make the soft tissue reconstruction more complex. An adequate appropriate debridement must be performed the first time. Repeated debridements “to make sure” are a result of an inadequate initial operation and massively increase delay and the infection rate. This should be avoided at all costs.

6 Establishing early bone stability is essential, and ideally the definitive bone stabilization should be performed at the primary procedure. This reduces the chance of late infection and facilitates the subsequent soft tissue reconstruction. In truth, the ability to perform an adequate debridement and the best bony reconstruction depends directly on the orthopedic surgeons’ confidence in the subsequent soft tissue closure and thus the working relationship with the plastic surgery team. While soft tissue reconstruction is often delayed for practical reasons there is excellent evidence that the earlier a healthy closure is obtained the better. This is true to the extent that the best data in the most complex (IIIb) injuries are with immediate flap cover after an adequate initial debridement and definitive bony reconstruction as one primary procedure (Fig. 28-3). Few units can achieve this at primary presentation, such that definitive debridement, fracture stabilization, and appropriate soft tissue assessment at the primary procedure followed by definitive soft tissue cover at the second visit to the OR (at about 48 hours) after the patient has been appropriately counseled are probably the best achievable standard. Cooperative care with the plastic surgical service from the start is essential.⁴⁴⁻⁴⁹

Table 28-5 Open Fracture Classification (after Gustillo & Anderson⁴³)

Grade I	Small low-energy wound, <1 cm no high-energy features
Grade II	Small low-energy laceration over fracture 1–10 cm no high-energy features
Grade IIIa	High-energy open fracture (degloving, periosteal stripping, bone comminution) with adequate soft tissue cover
Grade IIIb	High-energy open fracture with inadequate soft tissue cover
Grade IIIc	Any open fracture with a vascular injury requiring repair for viability

Vascular Injuries

An acutely ischemic limb with a fracture or dislocation is major surgical emergency. At presentation, all fractures must have the distal circulation assessed and documented; if the blood supply is affected the fracture or dislocation must be rapidly reduced. Fortunately, this commonly results in restoration of circulation and normal fracture care can continue. If not an emergent, combined vascular–orthopedic procedure is required. Sometimes a temporary shunt will be used to obtain distal flow while a bony reconstruction is performed. Bony stability at the correct length must be obtained before definitive vascular reconstruction, both to allow the vascular repair to be at the correct level and tension, and to protect it from disruption. Any subsequent reconstruction must be done with provision for awareness and care of the vascular repair.

Compartment Syndrome

A compartment syndrome is a major surgical emergency as the muscle is acutely ischemic due to an increased compartment pressure reducing tissue perfusion to below a critical level. Accordingly, the classical presentation is pain out of proportion to the injury due to the muscle ischemia. The compartment may be obviously hard with loss of muscle function and distal neurologic symptoms due to pressure on the nerves passing through the compartment. Loss of arterial flow through the compartment is exceedingly rare and not useful diagnostically, the presence of a distal pulse does not contribute to the diagnosis of compartment syndrome. While the diagnosis is often clinical and straightforward a formal measurement of the perfusion pressure of the compartment (similar to CPP in head injuries) has been popularized by McQueen.⁵⁰ Assessing mainly the anterior compartment of the lower leg after tibial fractures with constant compartment pressure monitoring, they showed that if the compartment pressure remained at least 30 mm of mercury below the diastolic blood pressure (known as the $Dp > 30$) the consequences of compartment syndrome (muscle necrosis and contractures) did not occur. Accordingly, today the definitive test for compartment syndrome is a direct measurement of the compartment pressure and comparison to the diastolic pressure. This is particularly seen in situations when the patient is not able to respond appropriately to pain. These include, during anesthesia, particularly under regional anesthesia, patients sedated on intensive care, patients where any strong analgesia is being used, or if the patient poorly responsive after a medication overdose. The diagnosis must not be missed, as immediate fasciotomy is needed to restore muscle perfusion.

Rarely compartment syndromes present late when muscle necrosis is established. There will be a high creatinine kinase level, myoglobinuria, and even frank renal failure if several compartments are involved and the presentation is delayed. If compartment syndrome is established at presentation, perhaps if diagnosed after 12 to 24 hours, fasciotomy is not indicated as it will only expose the necrotic compartment to infection. Unless deemed that muscle debridement is the only way to reduce the myoglobin level and reduce the renal damage the tight limb should be simply observed and the subsequent distal contracture more safely dealt with later by specific muscle or tendon releases.⁵²

Figure 28-3. A–E: Management sequence of a major open fracture. This is a III-C injury in a 12 year old treated by immediate “fix and flap” incorporating the anastomosis for the Lattimus Dorsi free flap into the vascular repair. The subsequent course shows good soft tissue and bony healing.

Indications for Amputation/Failure of Reconstruction

The indications for amputation can be remembered as the three “D’s” referring to a limb that is “Dead,” “Dangerous” or a “Damn” nuisance. In the early trauma situation, this may be clearly obvious and early amputation may be lifesaving while the latter refers to later reconstructive scenarios. While limb salvage is always an aim the surgery required may be protracted such that salvage should not be attempted if it puts life at risk. This requires experienced decision making at the acute stage and when possible agreement between staff surgeons. With an isolated injury situation, the decision essentially depends on the degree and site of necrotic tissue and reconstructive functional potential of the limb. If not grossly necrotic, this can be a most difficult decision and should be made by a surgeon experienced in reconstructive options and their functional outcome. In many situations, an amputee will function as well if not better than a poor reconstruction especially if several muscle compartments have been lost. This is clearly a decision for experienced staff and should involve the patient as much as possible. The application of a temporary external fixator to the severely mangled limb with a view to appropriate discussion prior to initiating a limb salvage course has much to recommend it.

ORTHOPEDIC TRAUMA SURGERY TO LIMIT DISABILITY – MANAGEMENT OF FRACTURES

7 The management of fractures has been a core medical discipline for millennia and has developed from primitive bone setting, through the guild of army barber surgeons to the modern day orthopedic traumatologist. In general orthopedic practice today, almost half of the work is the care of injury and in most the modern trauma centers taking a large percentage of blunt trauma 80% to 90% of the surgical care of the injured falls to the orthopedic service.

Fortunately, fractures have an intrinsic tendency to heal and bone is one of only two tissues to heal by reforming its own tissue and not with a scar. There are four essential phases in fracture management: assessment, position, healing, and rehabilitation. The first is self-explanatory but mandates a full limb assessment with documentation of the relevant clinical signs. This must include assessment and documentation of the neurovascular state of the distal limb. X-rays need to be taken of the whole bone involved and centered on the fracture. For example, an x-ray of the humerus which includes the shoulder is inadequate to assess a specific shoulder injury and separate views of the relevant part must be obtained. These views must include an AP and appropriate lateral. In many situations, the anatomy is still not adequately defined by these views and specific additional x-ray views or a computed tomography (CT) scan will be required to detail the anatomy to fully understand the injury and for

surgical planning. Fracture management then centers on obtaining and holding the position of the fracture through healing. Essentially middiaphyseal fractures need to be held in a position to maintain overall length, alignment, and rotation but do not need an anatomical reduction of individual fragments. They are usually treated by long bridging techniques that hold the bone at each end without an open reduction of the fracture area. In modern practice, this is usually achieved by intramedullary nailing which also provides the relative stability needed at the fracture site and facilitates healing with callus (Fig. 28-4). As a contrast, articular fractures usually need a direct open approach to ensure accurate reduction of the joint surface and the absolute stability of the fixation. The recovery of joint function is directly related to the quality of the reduction and provision of stable fixation to allow early motion. In this situation, the bone at the joint would be expected to heal by primary bone union without callus (Fig. 28-5).

Essentially, the method chosen to hold the position of the fracture will be more or less stable depending on how firmly it holds the bone. A traditional cast on the tibia will provide only relative stability but should lead to a high rate of healing with callus. There can be a very good functional recovery if an adequate position is maintained and cast complications are avoided but it essentially provides a less reliable hold than an implant directly applied to the bone. Accordingly, the patient undergoing nonoperative management in cast has to be followed closely, often with weekly x-rays for up to a month or until the position is deemed stable. The cast then stays until bone healing is considered adequate to maintain the position faced with functional loads and the cast can be removed. A stable, painless fracture on clinical examination suggests adequate healing to stay out of cast which should be confirmed by good bone healing on x-ray.

Nonoperative fracture management is an art that has been practiced for years but is used today only for stable relatively undisplaced fractures. This includes undisplaced articular fractures, low-energy nonarticular fractures, and many fractures in children who have a large capacity for remodeling during and after bone healing and obtain bony healing in about half the time adults with excellent function results (Table 28-6).

The phase of bone healing from fracture to a stable skeleton progresses from an inflammatory reaction through fibrous tissue and cartilage formation before immature bone and finally mature remodeling. A number of biologic stimulatory molecules and specific mechanical features then drive the normal healing response. Overall there is a progressive stiffening of the fracture environment until bone can form when the local strain is at or below 2%.^{53,54} This may be produced by the gradual tissue stiffening provided by the natural healing process or by an orthopedic implant that creates a local strain environment in conjunction with the specific fracture anatomy and intrinsic fracture stability. Normal healing with splintage or with devices that produce relative stability (some fracture motion under physiologic loads) lead to the progressive stiffening effect described briefly above and healing by callus when the strain reduces to a level where bone can form. If an implant confers absolute stability, usually through direct compression of the fracture surfaces, the strain is less than 2% from the start and the bone heals by a modified remodeling process termed “primary bone healing,” callus does not form. In planning a bony reconstruction the surgeon specifically decides what degree of stability is required to treat a specific fracture and the appropriate implant to do this. This follows basic AO^{55,56} principles which are the key to fracture surgery. Essentially, diaphyseal fractures need treatment with relative stability and indirect reduction techniques to maximize the local healing process. In contrast, articular fractures require usually a direct reduction for perfect anatomy and subsequent fixation with absolute stability (no deformation occurs under physiologic load) to facilitate joint recovery.

The rehabilitation process should be considered from the immediate decision-making process and begins as soon as the soft tissues are stable enough to allow dependency and joint motion. This confers the major advantages of mobility to the limb and whole patient. With articular fractures the cartilage is only nourished by diffusion from joint fluid which is effectively pumped into the hyaline cartilage as a secondary effect of motion. Accordingly, fracture fixation must be stable enough to allow early range-of-motion (ROM) exercises as tolerated but weight bearing is usually limited to protect the reconstruction from early displacement.

Figure 28-4. Assessment and surgical management of a diaphyseal fracture of the femur. **A,B:** Anteroposterior x-rays of a diaphyseal femur fracture **C,D:** Reamed fully locked intramedullary nailing of a diaphyseal femur fracture showing progressive healing.

Complex Articular Fractures

Major joint injuries are significant joint-threatening injuries and can be very complex.^{57–59} The aim of care involves articular reconstruction with perfect joint anatomy and stable fixation with absolute stability. Surgical reconstruction often requires detailed preoperative assessment with a CT scan and application of specific implants often designed for the specific joint and side involved. The basic principles used for surgical reconstruction of these injuries were developed over 50 years ago by the AO and have only seen minimal modifications since. However, modern implants and particularly the development of locking plates have improved the capability of our implants to hold fractures securely and specifically a cantilever hold of local fragments that allows fractures to be held well in position with less extensile exposures. The modern implant offers major mechanical advantages and the more limited approach reduces the chance of additional surgical damage to the injured bone and thus maximizes its healing potential. Occasionally the primary injury (even if closed) is associated with significant degloving of the local soft tissues, manifest by early fracture blisters and precludes an early open surgical approach.⁶⁰ Surgical management then takes the form of temporary bridging external fixation, applied outside the zone of injury which confers some stability and allows the soft tissues to settle prior to conversion to an internal fixation often after 1 to 2 weeks. However, in most fractures excellent results can be obtained by much earlier surgery which is much easier than a delayed reconstruction.⁶¹

Special Fracture Groups – Proximal Femur

Like many injuries, fractures of the proximal femur have a bimodal distribution with rarer high-energy injuries in the young and extremely common bone fragility fractures in the elderly. As a public health

issue, osteoporosis and its related fractures are at epidemic proportions with many fracture units admitting one or two patients every day.⁶² The general medical care of the elderly dominates the clinical picture where across the board the mortality is of the order of 15% to 20% in the 3 months after fracture. Major efforts to optimize the care of this group of patients are essential both on an individual and community basis. Massive numbers of injured frail elderly patients produce a major load on hospital and rehabilitation services. In addition, specific attention to long-term bone health is essential. The orthopedic issues of proximal femoral fracture take two forms and produce specifically different problems and solutions. The fractures essentially occur inside (intracapsular) or outside the hip capsule (extracapsular). Intracapsular fractures carry a risk of avascular necrosis (AVN) of the femoral head depending on the displacement of the fracture, while intratrochanteric fractures are mechanically unstable due to the anatomy and offset of the proximal femur creating marked mechanical instability with a tendency to collapse into varus.

Figure 28-5. Assessment and surgical management of a complex articular fracture of the distal tibia (pilon). Despite virtually anatomic reduction it progresses to degenerative arthritis in the medium term. **A,B:** AP and lateral x-rays of an intra-articular fracture of the distal articular surface of the tibia. **C,D:** CAT scans show the marked damage and displacement at the joint surface, underappreciated by initial x-rays. **E:** Open reduction and internal fixation to restore the joint surface for function and joint longevity. **F:** After healing and removal of the majority of the hardware there is significant degenerative arthritis of the joint that may need joint arthrodesis.

Table 28-6 Bone Healing Timeframes

Guideline Fracture Healing Times (In Cast)	Upper Limb	Lower Limb
Children	3 wks	6 + wks
Adults	6 wks	12 wks

Intracapsular fractures (femoral neck) are classically classified by Garden.⁶³ Garden grade 1&2 injuries are essentially undisplaced and carry a low risk of AVN, they are usually treated by fixation unless the patient's bone quality is considered too poor for fixation. In that situation and in displaced fractures (Garden grade 3&4) a replacement of the femoral head with hemiarthroplasty or total hip replacement in a biologically younger patient is required.^{64,65}

Extracapsular fractures (trochanteric) are mechanically unstable. They will collapse into varus without fixation and have a tendency to settle and shorten with healing due to the intrinsic bone weakness and pull of local muscles. Accordingly, fixation devices need the ability to mechanically control the angle of the femoral neck and accommodate some shortening without protrusion of the device into the hip. The instability is associated with the degree and position of any comminution which also indicates which device is appropriate to use. Essentially a sliding hip screw device can be used for any trochanteric fracture unless the lateral wall is incompetent (reverse obliquity injuries or their equivalent) or where there is subtrochanteric extension. In these cases an intramedullary nail with a retrograde locking device is specifically indicated although many surgeons use these nails for most fractures. When using a sliding hip screw for a trochanteric fracture it is essential to get the tip of the screw within a 1 cm of the articular surface to avoid failure.^{66,67}

Complications

Infection Nonunion and Malunion

Specific healing problems may require later specialist care.⁶⁸ Infection is unfortunately common after complex fracture care, especially if the initial injury was open. Failure of healing (nonunion) is not usually diagnosed before 6 months and commonly suggested by persistence of pain on loading and failure of progression of bone healing on x-Ray. Malunion is assessed with regard to the specific problem produced and may require specific corrective surgery for limb alignment, joint function, or longevity. While these complications are minimized by good primary fracture care, they still occur and many specialist services attract referrals of these problems. Commonly they are combined with infection and failure of bone healing often occurring together. In principle, infection after fracture creates a similar situation to osteomyelitis with acute and chronic clinical pictures. In general, the management of infection involves the same principles as the management of open fractures with debridement and lavage, skeletal stability and healthy soft tissue cover; with the addition of long-term antibiotics guided by perioperative cultures and under the supervision of an infectious disease specialist. Again adequate debridement of the poor often dead infected bone, the provision of bony stability and healthy soft tissue cover is the key to management.

Surgical management of the acute infection before fracture healing involves urgent washout of the wound, biopsy, cultures, appropriate antibiotics, and healthy wound management, often necessitating delayed primary closure after a secondary washout. While unstable fixation should be removed and stability regained stable fracture fixation should be maintained even if superficially contaminated until adequate fracture union. An implant can then be safely removed and usually any residual infection eradicated. Chronic infection with a united fracture needs similar treatment but in this scenario the fracture is stable. The key here is removal of a contaminated implant and debridement of dead bone to remove the source of infection. Subsequent, local profuse washout and healthy soft tissue closure then proceeds as above. However, in the chronic situation affected tissues are stiff and nonpliable such that bone and soft tissue debridement may produce a dead space, soft tissue defect, or skeletal instability with a bony defect. Filling a soft tissue defect will require appropriate soft tissue to be imported and commonly the help of a plastic surgeon. If a bony defect is created there are multiple potential options for treatment ranging from bone grafting through use of a cement spacer and the Masquet technique⁶⁹ to bone transport with an Ilizarov device.⁷⁰ or complex free bone/soft tissue transfer. Unfortunately, often limb salvage may end up being protracted and not be the best option for the patient.

Malunions cause considerable disability and can be very rewarding to correct (Fig. 28-6). Each needs to be fully assessed for the specifics of the deformity and consideration to a variety of methods of correction given. There are champions of a variety of acute correction methods with an osteomy and fixation or gradual correction usually with a ring fixation device.

Figure 28-6. Assessment and surgical management of a proximal femoral malunion after implant failure. **A:** Proximal femoral malunion (collapsed in to varus) with a broken implant in place. **B:** Correction of the malunion with a Valgus osteotomy held with a blade plate.

Orthopedic Injury/Disaster Triage

Given the predominance of orthopedic injuries in the injured patient and the frequency of multiple patient events surgeons are often faced with prioritizing the care of a number of injuries in one complex patient or of a number of patients at the same time. In common day practice a major motor vehicle crash with several victims can stress a system and require appropriate prioritization. In major international disasters these situations can be extreme. In these situations simple reliable rules are needed to guide staff through the process especially when there are multiple problems to consider and the situation is critical. ATLS dealt with this superbly with the A, B, C, alphabetic system for the primary survey. While this remains an excellent system for initial patient evaluation and can guide some immediate surgical decisions it does not help the surgeon who will have to make critical priority decisions beyond this. From the orthopedic traumatology point of view the variety of injuries often cover the whole spectrum of clinical need and produce complex decision-making situations. The easiest way for the supervising surgeon to plan the care of an individual is to stand back and work along simple priority guidelines, asking “what is needed here to save the life,” “what is needed to save a limb,” and “what is disability limiting.” Considering each injury in turn then allows a logical plan to be made to prioritize the care required. In multiple patient scenarios the process is the same but modified by the number of patients involved and the medical resources available. With adequate resources each patient’s problems are dealt with individually as needed and no consideration to major disaster triage is required. If resources are reasonable although stressed, patients with life-threatening problems are dealt with first prioritized by their individual acuity while others with important but initially stable issues can be managed safely later. In the massive disaster situation priorities change, resources are overwhelmed, and first priority is given to the group of patients who will gain the most while not tying up or exhausting scarce resources. The critical patient who would often be dealt with first when if more resources were available are not prioritized as their care would swamp the resources available and not allow simpler care to many others.⁵² Going in to situations (such as the immediate medical relief after the 2010 Haiti earthquake) without preplanning or the experience to deal with difficult decisions like this is not advisable.

Chapter 29

Pediatric Trauma

Elizabeth S. Soukup and Peter T. Masiakos

Key Points

- 1 Epidemiology:** Pediatric trauma significantly impacts the lives of children and families in the United States and around the world. Traumatic injuries remain the no. 1 killer of children and adolescents in the United States. Injury, both intentional and unintentional, accounts for more than 50% of deaths in children younger than 18 years. Therefore, pediatric trauma is a significant public health problem, with management strategies that should include not only emergency medical care but also injury prevention and systems of trauma care to meet the needs for pediatric patients.
 - 2 ABCs:** As in adults, the primary survey should focus on the identification of acute life-threatening injuries. Attention to the airway, breathing, and circulation (ABCs) supersedes all other interventions in the initial resuscitation phase. All centers that care for children should have sequestered resuscitation equipment designed for children, that is, endotracheal tubes, laryngoscopes, catheters, and passive warming lamps. Room temperature should be kept warm to limit insensible heat losses in small children. The Broselow Pediatric Emergency Tape aides in estimating the weight of the child by measuring his or her length and is used to facilitate pediatric resuscitation.
 - 3 C-spine clearance:** Much of the imaging that is done to clear the c-spine in a child is unnecessary. The clinical evaluation of pediatric trauma patients with suspected c-spine injury is quite effective in predicting which subset of patients will benefit from cross-sectional imaging. Simple clinical criteria, like Glasgow Coma Scale, used in concert with the physical examination, can safely predict cervical spine injury in children, safely reducing the dependence on clinical imaging for the vast majority of patients (even the very young).
 - 4 Nonaccidental trauma:** Nonaccidental trauma is a leading cause of trauma in children, with 650,000 confirmed cases of physical abuse annually in the United States, accounting for 1,500 deaths per year, mostly in children younger than 4 years.¹⁰⁵ Nonaccidental trauma and abuse may be difficult to recognize, and a high index of suspicion is needed when evaluating children with injuries. The American Academy of Pediatrics guidelines published in 2015 provide a resource to help identify these children, because unrecognized cases of abuse can represent with serious or even fatal injuries.
 - 5 Injury prevention:** As policy makers struggle to allocate limited resources in order to improve population health, injury prevention programs will play a particularly important role. The rationale is straightforward: regulatory efforts specifically aimed at injury primary and secondary prevention, if well designed, can be very successful at health care cost reduction, thereby freeing resources for other concerns.
-

INTRODUCTION AND EPIDEMIOLOGY

1 Pediatric trauma significantly impacts the lives of children and families in the United States and around the world. Traumatic injuries remain the no. 1 killer of children and adolescents in the United States. Injury, both intentional and unintentional, accounts for more than 50% of deaths in children younger than 18 years.¹ The pediatric mortality rate from trauma in the United States is double that of other developed countries, and for every pediatric death there were more than 2,000 emergency department visits.² In the United States alone, more than 50,000 children are permanently disabled after trauma, most commonly the result of traumatic brain injury (TBI).² Injuries account for almost a third of the total burden of disease in children by disability-adjusted life years.² According to data that are now longer than 20 years, these disabilities account for \$14 billion in lifetime medical spending and \$66 billion in future wages lost.³ Therefore, pediatric trauma is a significant public health problem, with management strategies that should include not only emergency medical care but also injury prevention and systems of trauma care to meet the needs for pediatric patients.³

Although there is a rise in the incidence of penetrating trauma, which now accounts for up to 10% to 20% of trauma activations, the vast majority of pediatric injuries result from blunt trauma with associated closed head injuries that require nonoperative management.

TRAUMA SYSTEMS

The concept of a trauma system was shaped by the publication of a US government report in 1966 “Accidental Death and Disability: the Neglected Disease of Modern Society”⁴ and has led to improvements in infrastructure, processes of emergency response, communication, and outcome measurements and quality indicators of responding hospital centers. The Committee on Trauma first categorized Trauma Center designations in 1976.² The first Pediatric trauma centers were organized in the 1970–1980s; however, even today in the United States, there are too few designated pediatric trauma centers to care for all pediatric trauma patients. There are 35 level I and 32 level II pediatric trauma centers verified by the American College of Surgeons and a handful of other pediatric trauma centers that are verified by their own states. Because the vast majority of pediatric patients are cared for at adult trauma centers,^{5,6} the exchange of ideas between adult and pediatric trauma centers and the development of integrated regional trauma systems remain critically important for our care of injured children.^{2,7}

Inclusive trauma systems include all facilities within a region according to a tiered-triage system. Each participating facility receives a level designation, and this is used to appropriately triage and refer patients as necessary. Along with these regionalization efforts, advances in pediatric transport have also improved how we care for injured children. Inclusive systems have been shown to improve outcomes because more timely and appropriate transfers can occur. It has become increasingly important to develop and study various “performance indicators” of the quality of care that is delivered to injured pediatric patients. For example, rate of successful splenic salvage is a commonly cited quality indicator in pediatric trauma, and there are reports that children cared for at an adult trauma center have a fivefold higher risk of splenectomy than those at pediatric trauma center.^{6,8,9} In addition, beyond simply benchmarking mortality rates, other measurable quality indicators include availability of a pediatric intensive care unit with in-house intensivists; radiation exposure from imaging; early neurosurgical intervention for severe head injury; early fixation of femur fractures; operative rates for solid organ injuries; and participation in registry databases to monitor performance over time, such as the Trauma Quality Improvement Program set up by the American College of Surgeons-Committee on Trauma.^{10,11} It is unclear whether superior care is offered to injured children in a dedicated pediatric hospital, compared to an adult hospital; however, it has been demonstrated that pediatric trauma certification and expertise in care of trauma patients are both important factors in optimal care.^{12–17}

Pediatric trauma centers should provide a broad range of pediatric-specific expertise, including pediatric emergency medicine, pediatric surgery and surgical specialties, pediatric anesthesiologists, and pediatric medical subspecialists, most importantly pediatric intensivists with a dedicated pediatric intensive care unit for intensive monitoring and care of critically ill pediatric patients. Furthermore, pediatric imaging protocols, sedation and pain management protocols, and overall principles of family centered care add a layer of safety to the care of the child. Child-life specialists and personnel to help transfer to posthospital all work to improve the care of the pediatric patient. The youngest and sickest children should preferentially be transferred to these higher-level designated pediatric trauma centers.³

INITIAL ASSESSMENT, RESUSCITATION, AND STABILIZATION

The evaluation and treatment of traumatic injuries of infants and children requires specific knowledge of pediatric physiology and the physiologic response to injury. Generally, the trauma resuscitation of children follows similar rules that have been described for adults by advanced trauma life support standards. However, there are several special considerations in the initial assessment and subsequent care for children and specific paradigms regarding ancillary studies that are different from those in adults. These special considerations will be discussed here.

Figure 29-1. Broselow pediatric emergency resuscitation tape.

2 As in adults, the primary survey should focus on the identification of acute life-threatening injuries. Attention to the airway, breathing, and circulation (ABCs) supersedes all other interventions in the initial resuscitation phase. All centers that care for children should have sequestered resuscitation equipment designed for children, that is, endotracheal tubes (ETTs), laryngoscopes, catheters, and passive warming lamps. Room temperature should be kept warm to limit insensible heat losses in small children. The Broselow Pediatric Emergency Tape aides in estimating the weight of the child by measuring his or her length. A color-coded bar on the tape measures the length of the child and indicates the appropriate equipment sizes and medication doses to perform emergency resuscitation on the child. Designated resuscitation equipment is contained in corresponding, color coded equipment pouches or drawers (Fig. 29-1).

Pediatric vital signs vary by age (Table 29-1). Children are able to maintain normal blood pressures until late hemorrhagic shock ($>30\%$ blood loss), and, therefore, subtle changes in heart rate and respiratory rate must be noted. As a general rule, the lower limit of acceptable systolic blood pressure = $\text{Age} \times 2) + 70$ mm Hg. For newborns, acceptable systolic blood pressure is 60 mm Hg or greater.

Airway control (“A”) is the first priority. Cardiac arrest in a child is most often of respiratory etiology, and an injured child who is obtunded, unresponsive, or combative may need to be intubated. An uncooperative child who needs radiologic imaging may also need to be intubated. Intubation must be performed with the jaw thrust technique and in-line cervical stabilization. Keep in mind these key anatomic differences for intubation in children: larger tongue, more narrow and anterior glottis, and shorter trachea. You may find that a straight Miller blade is easier than the curved Mac blade because the epiglottis is floppy (less cartilaginous). The appropriate size of ETT can be estimated by the size of pinkie finger (or the formula = $[\text{age} + 16]/4$). The Broselow Pediatric Emergency Resuscitation Tape is also a useful tool to estimate ETT (and other device) size and medication doses, given a child’s height or weight. Use an uncuffed ETT in a young child (<8 years of age or approximately 60 lb), because the subglottic trachea is narrow and provides a sufficient seal. However, cuffed ETT may be used (except in newborns), if appropriate cuff pressures are used. Rapid sequence intubation is similar to adults, including preoxygenation with 100% FiO_2 , medication administration, cricoid pressure, cervical spine stabilization, laryngoscopy, and advancement of tube to an appropriate distance beyond the cords. Confirm exhaled CO_2 and secure the tube. In the rare event of acute airway obstruction, needle cricothyroidotomy with a 14 g catheter is preferential to open cricothyroidotomy because of the increased incidence of subglottic stenosis.

Table 29-1 Pediatric Vital Signs

	Pulse (Beats/Min)	Systolic Blood Pressure (mm Hg)	Respiration (Breaths/Min)
Newborn (<1 mo)	95–145	60–90	30–60
Infant (1 mo to 1 yr)	125–170	75–100	30–60
Toddler (1–2 yrs)	100–160	80–110	24–40
Preschool (3–4 yrs)	70–110	80–110	22–34
School age (4–12 yrs)	70–110	85–120	18–30
Adolescent (>12 yrs)	55–100	95–120	12–16

Figure 29-2. A: Intraosseous line placement. B: EZ-IO drive.

After securing the airway, assess the child's breathing ("B"). If there is difficulty with respiration, assist the ventilation and assess for potential life-threatening thoracic injuries: pneumothorax (open chest wound or tension pneumothorax), hemothorax, flail chest/pulmonary contusions, and rib fractures with splinted breathing. The mediastinum of a child is very compliant and can lead to rapid decline from a tension pneumothorax. These life-threatening injuries must be rapidly identified and treated. Children are diaphragmatic breathers and, therefore, gastric distension can be an unrecognized contributor to respiratory distress, especially in the young child who is distended from swallowing air while crying. If there are concerns for abdominal distension, a nasogastric tube should be placed to decompress the stomach. Use an orogastric tube in babies, who are obligate nose breathers.

Hemorrhage is the most common etiology of Circulatory compromise ("C") in trauma, but do not overlook obstructive etiologies (cardiac tamponade and tension pneumothorax) and distributive etiologies (neurogenic shock). Assessment of volume status and shock is difficult in the child. Children have impressive physiologic reserve and can maintain systolic blood pressure until late-stage hypovolemic shock ($>30\%$ blood loss). Tachycardia, tachypnea, altered level of consciousness, and poor peripheral perfusion (mottled cool extremities, weak thready pulses, narrowed pulse pressure, delayed capillary refill) are early but subtle signs of blood loss. Establishing vascular access in an injured child is a priority and can be challenging. Peripheral intravenous lines are ideal, but when they cannot be obtained, intraosseous lines are quick, reliable, and allow high-volume infusion of any fluid (crystalloid, blood products, and even medications, including pressors). An intraosseous line is placed in the anteromedial tibia, 2- to 3-cm distal to the tibial tuberosity after a quick skin preparation for sterility (Fig. 29-2). Avoid wounds, fractures, or infected areas. They should ideally be placed with a single attempt because multiple holes can lead to leakage of infusion fluids and resultant compartment syndrome. If contraindicated, definitive intravenous (IV) access can be obtained with a central line in the femoral vein or a peripheral vein cut down (i.e., saphenous vein).

Initial fluid resuscitation is indicated when there are signs of hypovolemic shock. Initial bolus consists of 20 mL/kg of warmed normal saline or lactated Ringer's solution. This may be repeated if there is no response or only a transient response. All subsequent volume resuscitation should be performed with blood products (10 mL/kg = "1 unit") (Table 29-2). If there is no time for cross-matched, type-specific blood, "O-negative" blood is indicated. Massive transfusion protocols may be initiated at this time if indicated and should include hemostatic resuscitation with packed red blood cells, fresh frozen plasma, and platelets, targeting high plasma-to-red blood cell and platelet-to-red blood cell ratios.¹⁸ In the most recent advanced trauma life support protocols, this has become known as "damage control resuscitation,"¹⁹ espousing permissive hypotension, minimizing crystalloid resuscitation, and promoting early blood product administration for the treatment of the lethal triad (acidosis, coagulopathy, and hypothermia) of severe uncontrolled hemorrhage. There is, however, no evidence-based support for permissive hypotension strategies in pediatric trauma patients. As in adults, ongoing hemodynamic instability from blood loss in a child must be controlled expeditiously. Sources of bleeding can be thought of in terms of body compartments: including the chest, peritoneal cavity, retroperitoneum/pelvis, femur fracture/thigh compartment, and external injury (especially the scalp). In an infant, prior to suture closure of the skull, intracranial hemorrhage may produce hemodynamic instability. Once resuscitated, maintenance fluid requirements (Table 29-2) can be estimated using the "4-2-1" rule and should be administered as D5 1/2NS (or D10 1/2NS for neonates).

Table 29-2 Fluid Management in Children

Resuscitation Fluids (NS or LR)	
If hypotension or signs of shock:	Bolus 20 mL/kg. Repeat if transient or no response and then switch to blood transfusions (10 mL/kg).
Daily Maintenance Fluid Requirements (D5 1/2NS or D10 1/2NS)	
Weight <10 kg	100 mL/kg/day
Weight 11–20 kg	1,000 mL + 50 mL/kg/day (for every kg over 10)
Weight >20 kg	1,500 mL + 20 mL/kg/day (for every kg over 20)

A brief neurologic assessment is part of the primary survey (“D” for disability). Head injury accounts for the highest degree of morbidity and mortality in children and is the principle determinant of outcome after trauma. However, children have the potential for more frequent and fuller recovery from even serious head injury, when compared to similar injuries in adults.²⁰ Therefore, careful attention to preventing secondary injury and maximizing tissue perfusion to the brain can greatly improve outcome. These secondary insults include ischemia, hypoxia, hypotension, hyperthermia, hypercapnia, acidosis, and increased intracranial pressure (ICP). The Glasgow Coma Scale (GCS) is modified in young children who are preverbal to measure neurologic function and prognosis. The motor response scale tends to provide the most reliable assessment of function in a preverbal or intubated child (Table 29-3).

In preparation for the secondary survey, the child must be Exposed (“E”) completely for a complete head-to-toe physical examination. Keep in mind that they also have a larger body surface area ratio and, therefore, lose heat and water quickly and can become hypothermic. Use warm fluids, bare huggers, warming lights, and warm ambient room temperature to prevent heat loss in a child and the secondary coagulopathy that is associated with hypothermia.

Only after the primary assessment is complete, and ABCs are secured, do we move on to the full secondary survey. In reality, with a team approach to management of the pediatric trauma patient, much of the supportive care happens concurrently with the primary and secondary surveys, including placement of intravenous lines, drawing laboratories, applying monitors and oxygen, and obtaining ancillary diagnostic tests. Adjunct diagnostic modalities and imaging may be used to provide additional information in the evaluation of a pediatric trauma patient. Although diagnostic peritoneal aspiration has been traditionally used to evaluate intra-abdominal injuries in the unstable patient, it has no role in the pediatric population where solid organ injuries are unlikely to require surgery. Focused assessment with sonography in trauma (FAST) examination has significant advantages over more invasive diagnostic maneuvers: the FAST examination can be performed quickly and exposes the patient to no potential harm from delay or ionizing radiation. However, children with intra-abdominal injuries are more frequently managed nonoperatively, and thus the need for rapid decision making regarding operative management is less common. Children also have a relatively higher incidence of solid organ injury without free fluid, and consequently, a negative FAST examination may not obviate the need for an abdominal computed tomography (CT) when there is a clinical suspicion of significant injury. The FAST examination should not be relied on as a stand-alone screening tool in the pediatric population.^{21,22} Findings from chest radiography, anteroposterior pelvis radiography, and the FAST examination, along with the primary and secondary surveys, guide decisions regarding further radiographic examination, including CT or plain radiography.

In addition to a full physical examination, a brief history is essential and is often provided by emergency medical services (EMS) personnel or the parents. An “AMPLE” history helps the provider focus on essential information such as Allergies, Medications, Past medical history, Last meal, and Events surrounding the traumatic incident. Blunt trauma is the most common mechanism after which children present for evaluation. Children are more prone to multisystem trauma due to their small body size and more compliant body (less protective bones, muscle, and torso fat). Blunt trauma can result in injury patterns that resemble penetrating injuries, without significant external signs of trauma. Careful attention to a bruise on the abdominal wall resulting from a bicycle handlebar should lead to a more thorough investigation of the abdomen. A lap belt mark across the abdomen may raise concerns of lumbar spine fracture (Chance fracture), with an associated risk of small bowel injury. A history of significant hemorrhage at the scene may instigate a more thorough investigation of the vessels in the proximity of injury in an otherwise hemodynamically stable patient who has no hard signs of vascular injury. Therefore, a thorough history, mechanism of injury, and focused examination of the entire child is mandated so that signs of forceful impact can be elucidated.

Table 29-3 Modified Glasgow Coma Scale in Children

	Infant	Child
Eye opening		
4	Spontaneous	Spontaneous
3	To verbal stimuli	To verbal stimuli
2	To pain only	To pain only
1	None	None
Verbal response		
5	Coos and babbles	Oriented, appropriate
4	Irritable cries	Confused
3	Cries to pain	Inappropriate words
2	Moans to pain	Incomprehensible sounds
1	None	None
Motor response*		
6	Moves spontaneously and purposefully	Obeys commands
5	Withdraws to touch	Localizes painful stimuli
4	Withdraws in response to pain	Withdraws in response to pain
3	Abnormal flexion posture to pain	Flexion in response to pain
2	Abnormal extension posture to pain	Extension in response the pain
1	None	None

*If patient is intubated, unconscious, or preverbal, the most important part of this scale is motor response and should be closely evaluated.

MANAGEMENT OF SPECIFIC INJURIES

Traumatic Brain Injury

Traumatic brain injury is the leading cause of death and disability in children,^{20,23,24} and is an important determinant of outcome. Physical abuse such as shaken baby syndrome is the most common cause of head injury in children younger than 2 years, and blunt head trauma from motor vehicle accidents, falls, or bicycle/pedestrian accidents are responsible for most injuries in children older than 2 years. Injury prevention strategies are necessary for improving outcomes of the primary TBI. However, reduction of secondary injury patterns is critical in children, who have impressive physiologic reserve and potential for rehabilitation after brain injury. Focus must be on preserving cerebral oxygenation and perfusion and mitigate toxic exposures to minimize secondary brain injury. This includes treating or preventing hypotension, hypoxia, hyper or hypocarbia, hyperoxia with generation of ischemia reperfusion free-radicals, hyperthermia, seizures, and intracranial hypertension.

Mild Traumatic Brain Injury

Children with minor head trauma can present the greatest challenge to emergency department personnel. Eastern Association for the Surgery of Trauma (EAST) guidelines define mild traumatic brain injury (MTBI) to be interchangeable with the term “Concussion,” involving a blunt force mechanism with alteration in brain function (i.e., GCS score of 13 to 15) but by definition must have a normal head CT if performed.²⁵ Significant brain injuries need to be identified early and treatment instituted rapidly. CT scans provide the most accurate and expeditious means of diagnosis but expose many pediatric patients to unnecessary radiation. Evidence-based clinical decision tools have helped identify the population of children who benefit most from radiologic evaluation. The TBI study group for PECARN (Pediatric Emergency Care Applied Research Network) has developed tools for assessment of children after blunt head injury.^{25–30} The “PECARN Rules,”²⁶ ([Algorithm 29-1](#)) identify children at very low risk (<0.05%) of having clinically important TBI requiring intervention. These patients can avoid CT and be discharged safely with appropriate instructions. Children with abnormal GCS score (GCS score of ≤14) or evidence of skull fracture are at the highest risk for clinically important injury and should be evaluated emergently by CT scan. If there is a history of loss of consciousness, severe injury mechanism, abnormal behavior to the parent or nonfrontal scalp location (<2 years), or vomiting and severe headache (≥2 years), then further observation or CT should be offered as reasonable management options. Subsequent analyses also identified children with only isolated loss of consciousness (and no other PECARN predictors) to be at very low risk for clinically important TBI.²⁷ Children with MTBI (GCS score of 14 to 15) who underwent CT can be safely discharged home without further neurologic monitoring, if their head CT scan is normal.^{25,28} Even those with an isolated skull fracture can be

discharged home from the emergency department with strict discharge instructions and return precautions.^{29,30,31,32} At this point, routine structural or functional imaging modalities such as magnetic resonance imaging, functional magnetic resonance imaging, or positron emission tomography for diagnosis or prognosis of MTBI are not supported.²⁵

Algorithm 29-1. PECARN rules to identify children at very low risk of clinically important TBI. CT algorithm for children younger than 2 years (A) and for those aged 2 years and older (B) with GCS scores of 14–15 after head trauma. ciTBI, clinically important traumatic brain injury; GCS, Glasgow Coma Scale; LOC, loss of consciousness. (From Kuppermann N, Holmes JF, Dayan PS, et al. Identification of children at very low risk of clinically-important brain injuries after head trauma: A prospective cohort study. *Lancet* 2009;374(9696):1160–1170.)

Prognosis and outcome in MTBI, especially as it relates to “return to learn or return to play” after concussion, is still hotly debated. Most studies agree that patients with MTBI return to baseline within 3 months (majority within 10 to 14 days), but certainly symptom resolution can take longer. Lingering symptoms of headache, dizziness, fatigue, sleep disturbance, impairment in memory and concentration, irritability, anxiety, or depression are referred to as the “postconcussive syndrome,” which is not a well-understood entity.²⁵ Standardized tools exist, such as the Immediate Postconcussion Assessment and Cognitive Testing Battery (ImPACT), to aid clinicians in functional assessment of patients with MTBI.³³ The well-known NCAA Concussion Study from 2003 found that high-level athletes were more likely to sustain repeat concussions, which were associated with a longer recovery time,³⁴ and it has been increasingly recognized that repeat concussions can have permanent and sometimes devastating effects. In 2010, the American Academy of Pediatrics officially endorsed the International Conference on Concussion in Sport recommendations for a graduated “Return to Play” protocol (available online: <http://www.ncbi.nlm.nih.gov/pmc/articles/PMC4004129/table/T1/>, last accessed April 5, 2016).^{35,36} The CDC HEADS UP guidelines also incorporate these recommendations³⁷ and provide resources for schools, coaches, and primary care providers on returning to school and sports after a concussion. Data are lacking in the efficacy of these guidelines and their role in preventing recurrent concussions.³⁸

Moderate to Severe TBI

More serious head injury needs to be evaluated and treated expeditiously. The GCS (and modified GCS for infants) is a universal tool that can be used for rapid assessment of neurologic function and is based on verbal response, motor function, and eye opening. Moderate TBI is considered GCS score of 9 to 12 or 13 and severe TBI includes GCS score of ≤ 8 , the definition of a coma. The goal of initial assessment and resuscitation in a severely brain injured patient is to minimize or prevent secondary brain injury. Attention to ABCs is critical, with maintenance of normotension and normoxia. Management of severe TBI in the pediatric intensive care unit is largely focused on management of elevated ICP and maintenance of cerebral perfusion pressure.³⁹ In 2003 and again in 2012, guidelines for the acute medical management of severe TBI in infants, children, and adolescents were published, which represented the first recommendations made specifically for pediatric patients (Tables 29-4 and 29-5).^{40–43} These guidelines, composed mostly of class II or III evidence, included recommendations on management of intracranial hypertension, hypoxia/airway management, indications for ICP monitoring, thresholds for treatment and management of cerebral perfusion pressure, and hypotension. It also addressed therapies such as cerebrospinal fluid drainage, hyperosmolar therapies, hyperventilation, barbiturates, decompressive surgery, temperature control, corticosteroids, and supportive care such as sedatives/neuromuscular antagonists and nutrition, although the guidelines are mostly based on expert panel opinion rather than large clinical trials. Prehospital management focused on the benefit of pediatric trauma centers rather than adult trauma centers for children with severe TBI. Supplemental oxygen should be administered. There was no superiority of endotracheal intubation versus bag-mask ventilation in the prehospital setting, but if endotracheal intubation is to be undertaken, specialized training and the use of end-tidal CO₂ monitoring is encouraged. Hyperventilation with hypocarbia (pCO₂ < 30 to 35) is to be avoided. There was class II support for ICP monitoring for children with GCS score of 8 or less; using an ICP threshold of 20 mm Hg and a cerebral perfusion pressure of 40 to 65 mm Hg; efficacy of hypertonic saline solutions in lowering ICP; and the role for decompressive surgery in the treatment of elevated ICP. From these guidelines, an algorithm for the management of acute intracranial hypertension was developed on the basis of the expert opinions of the committee (Algorithm 29-2), which has served as a template for clinical protocols for patient care and research. The 2012 guidelines changed a few of the recommendations (Table 29-5). Only hyperosmolar therapy was supported by two small studies (class II data); the remaining therapeutics could not be supported by the literature, including use of corticosteroids, immune-modulating diets, and induction of moderate hypothermia (“Cool Kids” trial).^{44,45} Other topics with class III evidence were added including advanced neuromonitoring (using a brain–tissue oxygen partial pressure of 10 mm Hg), neuroimaging (avoiding routine repeat head CT unless neurologic deterioration), cerebrospinal fluid drainage, and the use of antiseizure prophylaxis (phenytoin prophylaxis) to reduce posttraumatic seizures. For a variety of other topics, including glycemic control, cerebrospinal fluid drainage, and analgesics/sedatives/neuromuscular blockade, definitive recommendations could not be made on the basis of the available literature. Overall, there is still a paucity of high-quality evidence to make specific treatment plans for children with severe TBI, but this allows for a wide variety of clinical approaches that are considered within the guidelines of pediatric care.

Spine Trauma

3 Cervical spine injuries (CSI) in blunt trauma pediatric patients occur in less than 2% of seriously injured children. Despite this low incidence, it is clear that many clinicians obtain radiographs in order to exclude CSI. The added benefit of routine imaging in the pediatric trauma evaluation is debatable. In recent years, concerns have been raised about the liberal use of plain films, CT scans, and magnetic resonance images in children with reference to imaging-related short- and long-term morbidity, resource consumption, and cost. The increased risk of fatal and nonfatal cancers associated with CT-related radiation has gained attention both by physicians and also by consumers. Both the U.S. Food and Drug Administration Center for Devices and Radiological Health (FDA) and the National Cancer Institute have published guidelines designed to limit unnecessary imaging in children. Although proponents of liberal imaging argue that a single missed CSI may cost more than multiple diagnostic tests, the use of non-evidence-based tests may inspire suboptimal practice with an undefined risk-benefit ratio.

Two seminal studies (NEXUS and Canadian Cervical Spine Rules [CCR])^{46,47} have examined whether clinical criteria (neurologic deficit, cervical spine tenderness, intoxication, decreased mental status, and distracting injuries) can rule out CSI in adults without the need of imaging. These criteria have been applied to pediatric patients in a manuscript by Viccellio and colleagues,⁴⁸ who evaluated 3,065 blunt

trauma patients younger than 18 years and found that nearly 20% of patients fell into the “low-risk” category where imaging could have been avoided. In another retrospective review of 206 pediatric patients (from birth to 16 years of age), Jaffe and colleagues⁴⁹ suggested that the absence of eight clinical criteria (neck pain; neck tenderness; abnormality of reflexes, strength, or sensation; direct trauma to the neck; limitation of neck mobility; abnormal mental status) enabled a clinician to detect CSI in children with a sensitivity of 98% and a specificity of 54%. The PECARN group has also reported on its series of 540 cervical spine injuries in children, presenting a model with eight predictors to identify children who should be evaluated for CSIs after blunt trauma.⁵⁰ These include altered mental status, focal neurologic deficits, complaint of neck pain, torticollis, substantial torso injury, predisposing condition, diving, and high-risk motor vehicle crash, with a sensitivity of 98%.

Table 29-4 Summary of Standards, Guidelines, and Options Generated from the 2003 Pediatric TBI Guidelines

Topic	Level of Evidence	Recommendation
Trauma systems, pediatric trauma centers, and the neurosurgeon	Guideline	“In a metropolitan area, pediatric patients with severe TBI should be transported directly to a pediatric trauma center, if available”
	Option	“...should be treated in a pediatric trauma center or in an adult trauma center with added qualifications to treat children in preference to a level I or II adult trauma center without added qualifications...”
Prehospital airway management	Guideline	“Hypoxia must be avoided...and attempts made to correct it immediately. Supplemental oxygen should be administered...no evidence to support an advantage of endotracheal intubation over bag-valve-mask ventilation...”
	Option	“If prehospital endotracheal intubation is instituted..., then specialized training and use of end-tidal CO ₂ detectors is necessary”
Resuscitation of blood pressure and oxygenation	Guideline	“Hypotension should be identified and corrected...defined as systolic blood pressure below fifth percentile for age or by clinical signs of shock...”
	Option	“Airway control should be obtained in children with a GCS ≤8 to avoid hypoxemia, hypercarbia and aspiration...hypoxia should be identified and corrected...blood pressure should be monitored frequently and accurately...”
Indications for intracranial pressure monitoring	Option	“ICP monitoring is appropriate...(GCS ≤8). The presence of an open fontanelle and/or sutures does not preclude the development of intracranial hypertension or negate the utility of ICP monitoring”
Threshold for treatment of intracranial hypertension	Option	“Treatment for intracranial hypertension...should begin at an ICP ≥20 mm Hg”
Intracranial pressure-monitoring technology	Option	“...a ventricular catheter or an external strain gauge transducer or catheter tip pressure transducer device is an accurate and reliable method of monitoring ICP”
Cerebral perfusion pressure	Guideline	“A CPP >40 mm Hg...should be maintained”
	Option	“A CPP between 40 and 65 mm Hg probably represents an age-related continuum for optimal treatment threshold...Hypotension should be avoided”
Sedation and neuromuscular blockade	Option	“...the choice and dosing of sedatives, analgesics and neuromuscular blocking agents...should be left to the treating physician...”
Hyperosmolar therapies	Option	“Hypertonic saline is effective at control of increased ICP...Mannitol is effective for control of increased ICP...”
Hyperventilation	Option	“...Prophylactic hyperventilation...should be avoided. Mild hyperventilation (PaCO ₂ 30–35 mm Hg) may be considered for longer periods of intracranial hypertension...Aggressive hyperventilation (PaCO ₂ <30 mm Hg) may be considered as a second tier option in the setting of refractory intracranial hypertension...”
Barbiturates	Option	“High-dose barbiturate therapy may be considered in hemodynamically stable patients with refractory intracranial hypertension...appropriate hemodynamic monitoring and cardiovascular support are essential...”
Temperature control	Option	“...Hyperthermia should be avoided...”
Surgical treatment of intracranial hypertension	Option	“Decompressive craniectomy should be considered...”
Corticosteroids	Guideline	“The use of steroids significantly reduces endogenous cortisol production...may have an associated increased risk of complications of infection”
	Option	“The use of steroids is not recommended for improving outcome or reducing ICP...”
Nutritional support	Option	“Replace 130%–160% of resting metabolism expenditure...nutritional support should begin by 72 h with full replacement by 7 d”

CPP, cerebral perfusion pressure (mean arterial blood pressure minus intracranial pressure); GCS, Glasgow Coma Scale; ICP, intracranial pressure; PaCO₂, partial pressure of carbon dioxide; TBI, traumatic brain injury.

Table 29-5 Summary of Evidence Generated from the 2012 Pediatric TBI Guidelines

Topic	Level of Evidence	Recommendation
Indications for ICP monitoring	Level III	"Use of ICP monitoring may be considered..."
Threshold for the treatment of intracranial hypertension	Level III	"Treatment of ICP may be considered at a threshold of 20 mm Hg"
Cerebral perfusion pressure thresholds	Level III	"A minimum CPP of 40 mm Hg may be considered...A CPP threshold of 40–50 mm Hg may be considered..."
Advanced neuromonitoring	Level III	"If brain oxygenation monitoring is used, maintenance of a partial pressure of brain-tissue oxygen (Pbto ₂) ≥10 mm Hg may be considered"
Neuroimaging	Level III	"In the absence of neurologic deterioration...routine repeat CT scan...may not be indicated..."
Hyperosmolar therapy	Level II	"Hypertonic saline should be considered...for intracranial hypertension...effective doses...range between 6.5 and 10 mL/kg"
	Level III	"Hypertonic saline should be considered...effective doses as a continuous infusion of 3% saline range between 0.1 and 1.0 mL/kg/h administered on a sliding scale..."
Temperature control	Level II	"Moderate hypothermia...for only 24 h duration should be avoided...moderate hypothermia starting within 8 h after injury and lasting for 48 h duration should be considered to reduce ICP...rewarming at a rate of 0.5°C/h should be avoided"
	Level III	"Moderate hypothermia...for 48 h duration may be considered"
Cerebrospinal fluid drainage	Level III	"CSF drainage through an externalized ventricular drain...may be considered...The addition of a lumbar drain may be considered..."
Barbiturates	Level III	"High-dose barbiturate therapy may be considered in hemodynamically stable patients with refractory intracranial hypertension...continuous arterial blood pressure monitoring and cardiovascular support to maintain adequate CPP are required"
Decompressive craniectomy for the treatment of intracranial hypertension	Level III	"Decompressive craniectomy with duraplasty...may be considered for pediatric patients...showing early signs of neurologic deterioration or herniation or are developing intracranial hypertension refractory to medical management..."
Hyperventilation	Level III	"Avoidance of prophylactic severe hyperventilation to a PaCO ₂ <30 mm Hg may be considered within the first 48 h...If hyperventilation is used...advanced neuromonitoring for evaluation of cerebral ischemia may be considered"
Corticosteroids	Level II	"The use of corticosteroids is not recommended to improve outcome or lower ICP..."
Glucose and nutrition	Level II	"The evidence does not support the use of an immune-modulating diet...to improve outcome"
	Level III	"...glycemic control...should be left to the treating physician"
Antiseizure prophylaxis	Level III	"Prophylactic treatment with phenytoin may be considered to reduce the incidence of early posttraumatic seizures..."

CPP, cerebral perfusion pressure (mean arterial blood pressure minus intracranial pressure); CSF, cerebrospinal fluid; CT, computed tomographic; ICP, intracranial pressure; PaCO₂, partial pressure of carbon dioxide.

Location of Injury

Conventional wisdom has taught that the position of a CSI in children was related to age with the predominance of upper c-spine injuries seen in infants and toddlers and lower c-spine injuries seen in adolescents. This was thought to be a result of the mechanism of injury (flexion/extension and axial load, respectively). However, in a recent evaluation of the pediatric national trauma database, Polk et al.⁵¹ identified a greater percentage of injuries to the lower c-spine than previously reported. A large database study evaluated the tendency for injuries to occur at certain levels of the cervical spine over a 5 year period and found that younger children (≤10 years of age) sustained upper (C1–C4) CSI more frequently than lower (C4–C7) CSI (87% vs. 57%).⁴⁹ Data from a 24-year retrospective study of patients admitted with CSI to a level 1 trauma center similarly concluded that for younger patients (≤8 years of age), significantly more injuries occurred in the upper cervical spine.⁴⁶ However, the National Trauma Data Bank (NTDB) data for this study revealed that the number of fractures to the upper c-spine and lower c-spine was nearly equal (53% and 47%), and that more than half of cervical spinal cord injuries were located in the lower c-spine (53%).⁵¹

Mechanism of Injury

Motor Vehicle Crash (MVC) remains the most common mechanism of CSI for the youngest age group.^{46–49,52} A study of children younger than 14 years observed that while MVC was the most common mechanism for this large age group, when ages were further stratified, MVC ranked the highest for infants.⁵³ This same study also found that falls were the most common mechanism for the 2 to 9 years age group. While the focus on children younger than 3 years in this study was unique, conclusions about mechanism of injury remained consistent with previous literature. The frequency of MVC as mechanism for blunt trauma CSI is significantly greater than all other mechanisms, with falls ranking second (66% and 15%, respectively). Given that this patient population is just learning to walk, falls are a concern. However, the high energy of an MVC has greater potential for major neurologic impairment and mortality.

The observations generated from analysis of the NTDB data suggest that the lower C-spine needs to be adequately evaluated on the basis of the near equal distribution of injuries. In addition, the association of CSI with high-energy mechanisms (i.e., MVAs) warrants a higher index of suspicion of this subset of young pediatric patients. In addition, those patients requiring at scene intubation and/or admission to the intensive care unit (ICU) should also be evaluated thoughtfully. Despite the low incidence of CSI, until the cervical spine is cleared, it should be immobilized, ideally with an age/size appropriate hard collar. Such collars should be stocked in all trauma centers that care for pediatric patients.

The authors of the reviewed paper⁵³ implemented a similar clinical guidelines strategy emphasizing the use of physical examination and NEXUS criteria in order to clear the cervical spine in children presenting after trauma. The primary outcome measure was to determine the use of CT scans in children younger than 15 years and to compare the extent of use of CT scans for cervical spine clearance 12 months before and after implementation of these guidelines. A total of 233 children were evaluated

during the 2-year period (128 before guidelines were in place and 105 afterward). For children clearable by NEXUS criteria, the implementation guidelines had an immediate effect, decreasing CT use by 23%. Furthermore, there were no missed injuries. These results offer even more evidence that much of the imaging that is done to clear the c-spine in a child is unnecessary. The clinical evaluation of pediatric trauma patients with suspected c-spine injury is quite effective in predicting which subset of patients will benefit from cross-sectional imaging. Simple clinical criteria, like GCS, used in concert with the physical examination, can safely predict CSI in children, safely reducing the dependence on clinical imaging for the vast majority of patients (even the very young).

Spinal Cord Injury without Radiographic Abnormality

Spinal cord injury without radiographic abnormality was first defined in a series of children with signs of acute traumatic spinal cord injury in the absence of bony findings on cervical spine radiographs, flexion–extension films, or CT scans.⁵⁴ The authors noted that these patients had neurologic deficits or a history of transient paresthesias, numbness, or paralysis, and a delay of symptoms occurred in approximately half of the patients.

In recent years, as attention to limit ionizing radiation exposure in children has increased, magnetic resonance imaging has become a mainstay in the workup of children with presumed CSI or neurologic deficits on physical examination. As a result, more children have been found to have demonstrable injury to the spinal cord, soft tissue components of the spinal column vertebral body growth plates.^{55,56} As a result of this advent of new neuroimaging paradigms, the diagnosis of spinal cord injury without radiographic abnormality has become questionable. Although the trend in the workup has been to limit radiography in children (with good reason), it is important to remember that young patients with blunt trauma who have a history of any transient neurologic symptom may have a significant injury to the spinal cord and/or spinal column, and these children warrant thorough radiographic evaluation.

Cerebrovascular Injury

Blunt trauma force to the neck or cervical spine fractures can result in vascular injuries to the carotid or vertebral arteries. Stroke and permanent neurologic deficit is the most feared outcome from this rare injury, and in children, because of ill-defined screening criteria, neurologic deficit is the most common presenting symptom for diagnosis. 2010 EAST guidelines are aimed at adult patients and provide little evidence toward screening criteria or management in either adults or children.⁵⁷ Risk factors for cerebrovascular injury include injury mechanism with severe hyperextension or hyperflexion with rotation, maxillary or mandibular injuries, TBI with diffuse axonal injury, near hanging, “seat belt sign” or other soft tissue contusion to the neck, and fractures involving the carotid canal or cervical vertebral body, particularly the vertebral foramen. A recent meta-analysis of pediatric blunt cerebrovascular injury recommended screening high-risk pediatric patients with CT angiography of the neck and treatment with anticoagulation in patients with confirmed injuries.⁵⁸

Thoracic Trauma

Blunt trauma, most commonly from motor vehicle crashes, is the most common mechanism for thoracic trauma in pediatric patients. Children have a more flexible, cartilaginous rib cage, and, therefore, serious intrathoracic injuries can occur in the absence of obvious external trauma or rib fractures. Children also have a more mobile mediastinum, predisposing them to tension pneumothorax with subsequent cardiopulmonary collapse from impaired venous return. The primary survey is designed to identify these acute life-threatening thoracic injuries such as airway injury, tension pneumothorax, open pneumothorax, hemothorax, flail chest with pulmonary contusion, or cardiac tamponade, which require immediate intervention (Table 29-6).⁵⁹ Once bilateral breath sounds and adequate ventilation and oxygenation are confirmed, CXR is an urgent part of any pediatric trauma evaluation and can identify most other acute thoracic injuries. FAST examination can evaluate for pericardial fluid and in experienced hands can identify pneumothorax or pleural effusion. Many injuries can be observed or managed with tube thoracostomy.

Pulmonary contusions are one of the most common thoracic injuries after blunt trauma. The diagnosis is made on CXR in which infiltrates are identified that do not follow anatomic boundaries. Parenchymal edema peaks at 24 to 36 hours postinjury, as the contusion “blossoms” on CXR, and requires admission for monitoring, oxygen therapy, or intubation and respiratory support if needed. Any evidence of hemothorax or pneumothorax seen on CXR should be managed initially with tube thoracostomy. Stable patients with an occult pneumothorax (seen only on CT scan but not on CXR) may be safely observed without thoracostomy drainage, even if requiring positive pressure ventilation. Traditional indications

for thoracotomy in adults include an initial chest tube output of 1,500 mL and a persistent output of 150 to 200 mL/hr for 4 hours. In children, this equates to a chest tube output of approximately 20% of the patient’s estimated blood volume, or ongoing output of 2 to 3 mL/kg/hr. However, patient physiology should be the primary indication for surgical treatment rather than the absolute blood output. The thoracoscopic approach has become increasingly acceptable in stable patients for the management of retained hemothorax, persistent air leak, or select diaphragmatic injuries after penetrating thoracoabdominal trauma. The EAST practice management guidelines for thoracic trauma provide a good overview of the evidence for management of thoracic trauma in adults, but no specific guidelines exist for pediatric patients.⁶⁰

Emergency bedside thoracotomy is indicated for patients who present pulseless to the emergency department with signs of life and penetrating thoracic trauma. The evidence is more controversial for patients who do not have signs of life or who sustained penetrating extrathoracic injuries or blunt trauma and should be based on clinical judgment. There is no role for emergency thoracotomy for patients without signs of life after blunt trauma.⁶¹ Advanced trauma life support guidelines recommend application of these guidelines to children on the basis of existing literature,^{62,63} but these data are sparse.

Table 29-6 Acute Life-Threatening Thoracic Injuries

Injury	Diagnosis	Management
Airway obstruction	Apnea or stridor, maxillofacial trauma.	Definitive tracheal intubation (oro- or nasotracheal) or cricothyroidotomy.
Flail chest	Paradoxical chest wall motion.	Positive pressure ventilation.
Tension pneumothorax (PTX)	Respiratory distress, tracheal deviation, hypotension, distended neck veins, absent unilateral breath sounds, hyperresonance to percussion.	Needle decompression (2nd interspace, midclavicular line), followed by placement of chest tube (4th interspace, anterior axillary line).
Open pneumothorax	Open wound into chest→“sucking chest wound.”	Sterile gauze (secure on three sides) and placement of chest tube.
Hemothorax	Absent breath sounds, dullness to percussion, hypotension.	Chest tube placement. Massive hemothorax necessitates thoracotomy.
Cardiac tamponade	Distended neck veins, muffled heart sounds, hypotension (Beck’s triad), pulsus paradoxus.	Pericardiocentesis (or emergency thoracotomy if pulseless).

Other serious thoracic injuries are very rare in children but include blunt aortic injury and blunt cardiac injury. Aortic injury can be effectively diagnosed with CT scan with IV contrast (CT angiogram). Widened mediastinum on CXR from a physiologic thymic shadow is quite commonly seen in young children. However, with the appropriate mechanism, including blunt thoracic trauma with a significant deceleration mechanism, and abnormal contour of mediastinum, CT chest angiography with contrast may be required to rule out this injury.^{64,65} Treatment, as in adults, relies on strict antihypertensive therapy and operative repair, including the endovascular approach in those children who are big enough to accommodate a stent (although this has not been standardized in pediatric patients). Blunt cardiac injury (most commonly myocardial contusion) can also be challenging to diagnose but occurs most commonly after motor vehicle collision or pedestrian trauma. Abnormalities on EKG are the main findings in myocardial contusion. Traditional risk factors such as sternal fracture or upper rib fractures do not appear to correlate with blunt cardiac injury. The new EAST guidelines, although designed for adult patients, recommend an EKG and troponin I if blunt cardiac injury is suspected. If both studies are normal, this effectively rules it out. If either is abnormal, the child should be admitted to a monitored bed. Echocardiogram is recommended only for patients with hypotension or arrhythmias.⁶⁶

Traumatic asphyxia occurs in children because of their flexible thoracic wall in the setting of direct blunt compression, most often after a motor vehicle collision or crush injury. At the time of injury, if the glottis is closed and the thoracoabdominal muscles are tensed, the increased intrathoracic pressure is transmitted through the central venous system (inferior and superior vena cava) to the brain and solid organs. Typical signs of traumatic asphyxia include subconjunctival hemorrhage and petechiae of the chest, shoulders, and head, with subsequent bronze discoloration of the skin. Supportive care in a monitored setting is the standard of care for these children, watching for signs of airway edema.

Abdominal Trauma

Blunt mechanism of injury is the most common cause of abdominal trauma in children. Assessment of abdominal trauma in pediatric patients can be challenging. Vomiting, abdominal tenderness, and seat belt signs are signs and symptoms that increase the likelihood of abdominal injuries. FAST examination

is a standard assessment in adult trauma patients, but its role in pediatric patients is still controversial. In an unstable patient, FAST examination can help identify the presence hemoperitoneum and triage a patient to the operating room or interventional radiology suite. CT scan with IV contrast is the best assessment for abdominal trauma in a stable pediatric patient. Despite concerns for radiation exposure, this is an important study if indicated. PECARN has similarly developed rules and algorithms to identify a low-risk patient who can safely avoid abdominal CT.^{67–69} If an examinable child (GCS score of >13) had no evidence of abdominal or chest wall trauma (including seat belt sign), no abdominal pain, tenderness or vomiting, and normal bilateral breath sounds, the rule had a 99.9% negative predictive value for intra-abdominal injuries requiring intervention^{67,69} and was more sensitive than clinical suspicion.⁶⁸ After a normal abdominal CT scan, most patients can safely be discharged if otherwise stable (sensitivity 97.8%). However, most missed injuries were hollow viscous injuries, which are difficult to identify on CT and should be suspected in patients with seat belt sign, free fluid on CT, or leukocytosis.⁷⁰

Penetrating abdominal trauma is much less common in children than in adults but should be managed similarly. There is increasing evidence toward a nonoperative, conservative approach to abdominal stab wounds that penetrate the fascia, relying on serial examinations and imaging to guide operative approach. Laparotomy is still largely recommended for gunshot wounds to the abdomen on the basis of the most recent 2010 EAST guidelines, although this area remains controversial.⁷¹

Damage control laparotomy is an established operative approach for hemodynamically unstable trauma patient in hemorrhagic shock and is utilized in approximately 5% of all laparotomies for trauma in both adults and children. The goal of this approach is to avoid the onset of the lethal triad: hypothermia, coagulopathy, and acidosis. The procedure is abbreviated and focused on maintaining the priorities of hemorrhage control, followed by control of contamination and temporary abdominal closure, with plans to return for definitive repairs after resuscitation and warming in the ICU, usually 24 to 48 hours later. The decision for damage control should be made early in the operative course in order to minimize exposure time in the operating room and avoid irreversible shock and its sequelae. Although well described and widely adopted within the adult trauma population, data are less available in the pediatric population but theoretically of even greater importance as children have small circulating blood volumes and are more prone to hypothermia.⁷² As discussed in a previous section, damage control resuscitation is managed in parallel, with a focus on initiating the massive transfusion protocol, minimizing crystalloid fluids, and resuscitating with blood products using a high ratio of plasma and platelets for each unit of red blood cells transfused.⁷²

Solid Organ Injuries

Most solid organ injuries (spleen, liver, and kidney) are managed nonoperatively after blunt trauma.⁷³ Most of these injuries are identified or evaluated by CT and can be graded according to American Association for the Surgery of Trauma (AAST) grading system for prognostic value.⁷⁴ In a large series of pediatric patient with solid organ injury, 11% received a blood transfusion, 1.4% underwent angiographic embolization, and 4% required laparotomy.⁷⁵ Laparotomy rates ranged from 5.4% at adult trauma centers to 2.8% at freestanding children's hospitals, raising concerns for optimal and consistent management of pediatric patients who are cared for in adult centers.^{75–77} Across all institutions, there is wide variability of care of pediatric patients with solid organ injuries. In those managed successfully with nonoperative management, there is no standard of care for level of monitored care (whether children are admitted to ICU vs. floor vs. home), frequency of blood draws, duration of bed rest or bowel rest, and timing of discharge home and resumption of activities.⁷⁵ In the 1990s, the American Pediatric Surgical Association proposed an algorithm for posttrauma management of solid organ injuries, which has commonly been adopted by institutions but has never been rigorously verified (Table 29-77⁸). These recommendations include ICU admission only for grade IV solid organ injury, observation on the pediatric floor for a duration of injury grade +1 days, liberation of diet and ambulation once the hematocrit has stabilized (and hematuria resolved in renal injuries), and exertional activity restriction for a duration of injury grade +2 weeks. No routine reimaging of injuries is recommended.⁷⁸ Indications for laparotomy include hemodynamic instability, ongoing blood loss (hematocrit drop) with blood transfusion requirement of greater than 20 mL/kg, or evidence of hollow viscous injury. More recently, the American College of Surgeons' pediatric trauma consortium (ATOMAC) developed a practice management guideline for solid organ injury, which is now used at many additional pediatric trauma centers throughout the United States.⁷⁹ The guidelines support management on the basis of hemodynamic status rather than injury grade. Transfusion triggers have

been debated and although there are no class I data to support a number at which blood should be given, it is generally agreed that transfusion should be considered at a threshold of 7.0 g/dL. It supports abbreviated bed rest and earlier discharge than the older APSA guidelines ([Algorithm 29-3](#)). The approach to angiographic embolization for splenic salvage is still controversial in pediatric patients and has a wide variability among institutions.⁷⁹⁻⁸²

Table 29-7 Original American Pediatric Surgical Association Guidelines for Posttrauma Management of Pediatric Solid Organ Injury

	CT Grade			
	I	II	III	IV
ICU stay (days)	None	None	None	1
Hospital stay (days)	2	3	4	5
Predischarge imaging	None	None	None	None
Postdischarge imaging	None	None	None	None
Activity restriction (weeks) ^a	3	4	5	6

^aReturn to full-contact, competitive sports (i.e., football, wrestling, hockey, lacrosse, mountain climbing) should be at the discretion of the individual pediatric trauma surgeon. The proposed guidelines for return to unrestricted activity include "normal" age-appropriate activities. From Stylianos S. Evidence-based guidelines for resource utilization in children with isolated spleen or liver injury. *J Pediatr Surg* 2000;35(2):164-169, with permission.

The role of FAST examination for diagnosis of solid organ injury in children is still unclear. Whereas its use has long been the standard of care in adults, recent PECARN data of pediatric trauma centers suggest that only 13% of pediatric trauma patients with a suspicion for intra-abdominal injuries undergo FAST examination.^{83,84} Sensitivity in pediatric patients ranges from 50% to 92%, with a rigorous meta-analysis suggesting the sensitivity to be around 66%.^{21,22,85-87} Specificity is also very low, and in a hemodynamically stable patient, a positive FAST examination should be followed up with an urgent CT. Bedside FAST may have utility in hemodynamically unstable patients to rapidly identify or rule out intraperitoneal hemorrhage when patients cannot undergo CT, but decision making should include other features such as patient physiology, mechanism, clinical suspicion, and responsiveness to initial resuscitation measures.^{22,88} As its use in children increases, it is likely that FAST will become more reliable, with greater sensitivity and specificity. Until a prospective study is done, it should remain a screening tool and that physical examination findings should dictate next steps.

Algorithm 29-3

Algorithm 29-3. New ATOMAC guidelines for management of pediatric solid organ injury. Hb, hemoglobin; ICU, intensive care unit; LR, lactated ringers; NOM, nonoperative management; NPO, non per os; NS, normal saline; PICU, pediatric intensive care unit; PRBC, packed red blood cell; q6h, every 6 hours. (From Notrica DM, Eubanks JW III, Tuggle DW, et al. Nonoperative management of blunt liver and spleen injury in children: Evaluation of the ATOMAC guideline using GRADE. *J Trauma Acute Care Surg* 2015;79(4):683–693, with permission.)

Hollow Viscous Injury

Hollow viscous injuries occur after blunt trauma, in particular bicycle handlebar injuries, lap belt injuries (often with seat belt sign and associated with Chance vertebral fracture), and direct blows to the abdomen. Diagnosis is challenging with current radiographic techniques. Subtle findings on CT must be elicited, including free fluid in the absence of solid organ injuries, free intraperitoneal air, or extravasation of oral contrast. In the setting of abdominal wall ecchymosis (seat belt sign), leukocytosis, or abdominal tenderness, patients should be closely monitored with serial abdominal examinations and blood count. Evidence for evolving peritonitis, fever, leukocytosis, or systemic inflammatory response syndrome physiology should prompt surgical exploration, either laparoscopic or by laparotomy. Intramural duodenal hematomas are managed conservatively without surgical intervention but may take several weeks to completely resolve, requiring nasogastric tube (NG) drainage and Total Parenteral Nutrition (TPN) in the interim. Delayed stricture after partial thickness luminal injury or mesenteric injury can present days to weeks after an injury, with symptoms of partial or complete small bowel obstruction.

Pancreatic and Biliary Injury

Pancreatic injury classification by AAST injury grade divides patients into those without ductal injury (grades 1 to 2) and those with duct disruption (grades 3 to 5). Currently there is no universal standard

for management of pancreatic trauma in pediatric patients, but evidence is beginning to emerge.^{89–97} Amylase and lipase are useful to screen for pancreatic injury but may be normal immediately after trauma; by 3 hours after trauma, they are universally elevated (100% sensitivity), although with low specificity.⁹¹ CT scan of the abdomen can help determine the integrity of the duct, but endoscopic retrograde cholangiopancreatography (ERCP) may be a useful adjunct in some patients. In general, higher-grade pancreatic injuries with duct disruption result more frequently in operative intervention. Although early literature promoted nonoperative management for pediatric pancreatic injuries,^{91–95} recent reports and multi-institutional studies have suggested improved outcomes, reduced need for drainage procedures, and decreased length of stay (LOS) for operative intervention, most commonly distal pancreatectomy.^{89,96,97}

Biliary injury is rare in children, representing <0.1% of all trauma patients, and includes intrahepatic and extrahepatic ductal injuries, biloma, and gallbladder injury. Literature is sparse but many injuries can be managed nonoperatively with ERCP with biliary stent placement and percutaneous peritoneal drainage. These patients are at risk for delayed stricture and require close follow-up. Hepaticojejunostomy remains the definitive repair for extrahepatic biliary tract transections.⁹⁸

Anorectal Injuries

Anorectal injuries are uncommon in children and usually occur after penetrating mechanism. Isolated anal trauma can be repaired primarily, including sphincter repair. Extraperitoneal rectal injuries should be repaired primarily if possible and often require fecal diversion and/or presacral drainage. Intraperitoneal rectal injuries can be managed similarly to colon injuries, with or without fecal diversion. Associated genitourinary injuries should be sought with examination under anesthesia.^{99,100}

Pelvic Fracture and Extremity Trauma

Fractures represent one of the most common injuries in pediatric trauma patients. Children have more malleable bones, more absorptive cartilage, and a higher potential for bone remodeling and healing than adults. Anatomic differences in radiology of pediatric bones can make recognition of injuries challenging. Injury to the growth plates can result in premature fusion and asymmetric limb growth. Greenstick fractures occur when the bone bends before it breaks. Options for stabilization include casting, splinting, traction, internal fixation, or external fixation. A thorough neurovascular examination is essential. Although vascular injury requiring repair is rare, children are more prone to vascular spasm, resulting in asymmetric pulse examination and transient ischemic symptoms.¹⁰¹

Pelvic fractures are a source of morbidity and mortality in pediatric patients and occur most commonly after high-mechanism blunt trauma such as MVC or pedestrians struck. Pelvic fractures are usually present in the setting of multiple injuries including TBI, abdominal injuries, and genitourinary trauma. The Young-Burgess Classification system for pelvic fractures is most commonly used in adults and categorizes injuries into lateral compression, anterior–posterior compression, and vertical shear injuries to the pelvic ring. Pediatric classifications exist but are not standard. The pediatric pelvis is more elastic, allowing for significant displacement before fracture. Pelvic hematoma and ongoing hemorrhage requiring angiographic intervention or preperitoneal packing occurs less commonly in children than in adults but should be a major consideration in the hemodynamically unstable child. The 2011 EAST guidelines for the treatment of hemorrhage in pelvic fracture are limited to adult data, but many principles can be extrapolated to the pediatric population.¹⁰² These guidelines recommend the use of early external stabilization, particularly with a size-appropriate pelvic orthotic device, to stabilize fractures, reduce pelvic volume, and theoretically limit blood loss. The hemodynamically unstable pediatric patient with a pelvic fracture represents a diagnostic challenge – does one proceed to the operating room for abdominal exploration or to the angiography suite for embolization? FAST examination does not have the sensitivity to rule out abdominal hemorrhage. If stable enough, a CT scan of the abdomen and pelvis is preferable to help identify the injuries and determine treatment course. Despite classification systems, fracture patterns on anteroposterior pelvic plain film do not predict bleeding or need for angiographic embolization. Angiographic embolization should be considered in hemodynamically unstable patients after other sources of hemorrhage have been ruled out. In the adult literature, arterial contrast extravasation on CT scan warrants empiric embolization, even in a stable patient, but these data are unclear in the pediatric population. Similarly, preperitoneal packing is a newer technique for the control of pelvic hemorrhage, and its use can be considered alongside pelvic embolization.¹⁰² Treatment of pelvic fractures in children is usually nonoperative with non-weight bearing, Spica casts, or traction. In some cases, external fixation or open reduction, internal

fixation (ORIF) is necessary. Fractures involving the acetabulum are complex, especially when the triradiate cartilage complex is involved, as premature fusion can result in long-term problems with leg-length discrepancy and acetabular failure.

Venous Thromboembolism

The incidence of venous thromboembolism in pediatric trauma patients is very low, ranging from 0.02% to 0.3%.¹⁰³ Although evidence in adult trauma populations supports chemical prophylaxis, such as low-molecular-weight heparin, no standard evidence-based guidelines exist for pediatric patients. Recommendations are based on small series and retrospective data. A recent meta-analysis and review of the literature suggests that older and more severely injured patients are at higher venous thromboembolism risk.¹⁰³ In particular, those with spine or spinal cord injury, or major vascular injuries are at the highest risk. Other risk factors include admission to an ICU, presence of a central venous catheter, lower extremity or pelvic fracture, or TBI, and when one or more of these are present, pediatric patients should be considered for prophylaxis. Clinical prediction tools based on large databases, such as the National Trauma Data Bank, have been proposed but require validation.¹⁰⁴

Nonaccidental Trauma (Child Abuse)

4 Nonaccidental trauma is a leading cause of trauma in children, with 650,000 confirmed cases of physical abuse annually in the United States, accounting for 1,500 deaths per year, mostly in children younger than 4 years.¹⁰⁵ Nonaccidental trauma and abuse may be difficult to recognize and a high index of suspicion is needed when evaluating children with injuries. The American Academy of Pediatrics guidelines published in 2015 provide a resource to help identify these children, because unrecognized cases of abuse can re-present with serious or even fatal injuries. Features of the history that should increase suspicion include unexplained significant injury, denial of trauma, changes in the story or differences in the story by different witnesses, explanation that is inconsistent with the pattern, age or severity of injury or with the child's developmental capabilities, and delay in seeking medical care. Findings on examination that may suggest abuse include any injury in a preambulatory infant, multiple organ system injuries or multiple injuries at different stages of healing, patterned injuries, injuries to unusual locations (mnemonic "TEN-4" = injury to torso, ears, or neck in a child younger than 4 years), or other evidence of neglect (failure to thrive, dental caries, poor hygiene). Burns with sharply demarcated edges, bite marks, cigarette burns, and other markers of being hit with an object are high-risk injuries. Certain fracture patterns should raise concern for nonaccidental trauma including fractures in nonambulatory infants, multiple fractures, rib fractures, infants and toddlers with midshaft femur or humerus fractures, and other unusual fractures such as scapular and metaphyseal fractures. Skeletal survey is recommended in children younger than 2 years who have suspicion for abuse (see Indications for Obtaining a Skeletal Survey available online from the study by Christian¹⁰⁵; see Skeletal Survey Guidelines available from the study by Wood et al.¹⁰⁶). If there is a reasonable suspicion that a child has been abused, a report to child protective services for further investigation is mandated by law. See Christian, CW¹⁰⁵ for outlines recommending workup in a child suspected of nonaccidental trauma, including blood work, imaging, and consultation of specialists such as ophthalmology, in order to identify injury and obtain forensic evidence.

INJURY PREVENTION

5 In 1911, the Triangle Shirtwaist Company in New York City's Greenwich Village became the site of the deadliest industrial disaster in US history. In a fire that engulfed the 10-story building, 146 sweatshop workers (mostly young women) died when elevators and fire escapes failed. Following this incident, the labor movement was born and policy makers began to take a hard look at working conditions and addressed safety in the work place by passing meaningful legislation. Although the concept of injury prevention legislation can be dated back to the early 20th century, it was not until 1964 when the four major US auto manufacturers installed two front-seat lap belts as standard equipment did injury prevention develop into a true science. In 1968, the National Traffic and Motor Vehicle Safety Act established the National Highway Traffic Safety Administration, which has influenced the improvement of road infrastructure, automobile, and driver and passenger safety, resulting in precipitous drops in roadway fatalities.

There are many examples where comprehensive state and federal laws have resulted in statistical

drops in injuries and deaths.¹⁰⁷⁻¹⁰⁹ In the following section, we provide several examples where federal mandates and state laws have been implicated in the reduction of pediatric injuries. In many cases, surgeon advocates were integral in the legislative process.

Smoke Detectors and Carbon Monoxide Detectors

Smoke detectors have been legislated into building codes in all 50 states. As a result, the early warnings of a fire are thought to have prevented thousands of deaths. More than 10,000 Americans are poisoned by carbon monoxide and more than 500 people in the United States die annually from carbon monoxide poisoning. As of August 2015, 30 states have enacted statutes regarding carbon monoxide detectors, and another 11 have promulgated regulations on CO detectors. Several states now require CO detectors in hotels and schools.

Drunken Driving Laws

Alcohol is known to play a role in many MVCs. Drivers younger than 21 years are more likely than older drivers to be involved in fatal crashes, and alcohol use adds to the risk of fatal crashes. This group has been the target of several interventions to reduce alcohol-impaired driving, including “zero tolerance” blood alcohol concentration standards for drivers under the legal drinking age with mandatory license revocation after a first offense.¹¹⁰

Junior Driver Laws/Safe Driving Laws

The increased risk of car crashes associated with texting and cell phone use has been well documented – among adults and teens alike. But for teens, who are immersed in a world of smart phones and texting, these types of laws send a powerful message that driving demands their undivided attention. Although not exclusive to children or adolescents, “safe driving laws” ban text messaging for all drivers, prohibit junior drivers from using cell phones, and institute new license renewal procedures for mature drivers, among other provisions. Graduated driver licensing programs that require new drivers to progress through stages allowing them increased driving privileges as they gain experience have, in some form, been enacted in all 50 states. Many states have also incorporated parental education and curfews to these laws and have seen up to a 40% decrease in the number of injuries and fatalities as novice drivers have become engaged in this process.^{111,112}

Child Passenger Restraints

Seat belt use around the country has steadily increased. There is mounting evidence that seat belt use and airbag implementation have been the greatest cause for decreased road fatalities per miles driven, which is at an all-time low according to National Highway Traffic Safety Administration statistics. Furthermore, there is evidence that educating pediatricians improves the use of car seats for children. Although the rate of use of car seats for newborns and infants is approximately 75%, their use in toddlers is estimated at only 29%, and more than half of car seats for children are not used correctly. In the child older than 4 years or 40 lb, there is ample evidence that booster seats should be used rather than adult-type restraints. Many states now have legislation aimed at this population.

All-Terrain Vehicle Laws

In the United States, all-terrain vehicle crashes account for a rising number of injuries and deaths in all age. Approximately 30% of the injured/dead are children. In 1988, in response to this trend, the Consumer Product Safety Commission and the all-terrain vehicle industry agreed upon a set of standards designed to limit injury. This agreement included regulations that restricted operators younger than 16 years halted the sale of three-wheeled vehicles and included a mandatory educational safety training module and improved safety warnings. However, in 1998, 10 years after they were established, these consent decrees expired and since that time, the rate of injuries has risen steeply. Several states have recently enacted restrictions on ridership and in Massachusetts, where these restrictions have included an age cutoff, the number of injuries have fallen dramatically (unpublished data).

Finally, as policy makers struggle to allocate limited resources in order to improve population health, injury prevention programs will play a particularly important role. The rationale is straightforward: regulatory efforts specifically aimed at injury primary and secondary prevention, if well designed, can be very successful at health care cost reduction, thereby freeing resources for other concerns.

Chapter 30

Geriatric Trauma

Carlos V.R. Brown, Zara Cooper, and Ali Salim

Key Points

- 1 The physiology of aging affects nearly every organ system including cardiovascular, pulmonary, renal, and gastrointestinal. Altered physiology may also be associated with comorbid conditions in the elderly patient including hypertension, cardiac disease, chronic obstructive pulmonary disease (COPD), chronic renal insufficiency, and altered drug metabolism.
 - 2 The American Geriatrics Society has published the Beers Criteria for potentially inappropriate medication use in older adults that can be used to refine inpatient medication management for elderly trauma patients.
 - 3 Falls are far and away the most common mechanism of injury in elderly trauma patients, causing almost 75% of injuries in elderly patients; 90% of elderly falls are ground level falls.
 - 4 An underreported but important mechanism of injury in elderly trauma patients is elderly abuse.
 - 5 Imaging with head CT in elderly trauma patients should be used liberally.
 - 6 Severely injured older patients may not display standard signs of hemodynamic instability.
 - 7 Due to the broad range of age-related factors that can contribute to injury and adversely affect recovery in geriatric patients, injured individuals should receive a comprehensive geriatric assessment during their hospital stay.
 - 8 Frailty is a syndrome of decreased physiologic reserve distinct from the normal aging process and other comorbidities. Frailty is associated with higher mortality and complications, and worse functional outcomes after trauma, and is more predictive than age or injury severity of hospital complications, in-hospital mortality, or discharge to an institution.
 - 9 Palliative care is appropriate in the management of a broad range of injured patients who die or suffer with acute and chronic pain, functional disability, or life-limiting conditions such as severe frailty and underlying organ failure.
 - 10 Four-fifths of in-hospital deaths among geriatric trauma patients involve decisions to withdraw or withhold of life-sustaining therapies.
-

INTRODUCTION

The elderly population in the United States is steadily growing and Americans >65 years old are expected to number more than 80 million by the year 2050, more than double the population in 2012.¹ Trauma and acute care surgeons will be increasingly responsible for caring for this complex population of patients. Even prior to injury, the elderly patient brings unique challenges including altered physiology, numerous comorbid conditions, and preinjury medications. The epidemiology and triage complexities of elderly trauma patients make it challenging to ensure these patients are transported to the appropriate receiving facility. Elderly patients are most often injured by a blunt mechanism and are particularly at risk for falls from standing. In addition, they sustain unique injuries that may escape diagnosis during the initial evaluation. Trauma centers may need to alter activation criteria for elderly trauma patients in order to avoid the pitfall of undertriage that is associated with poor outcomes in this population. Though the initial trauma evaluation for elderly patients is similar to younger adults, the trauma surgeon must understand the nuances associated with caring for the injured elderly patient. The elderly trauma patient more frequently has issues that relate end-of-life care in the postinjury period.

PHYSIOLOGY, COMORBIDITY, AND PREINJURY MEDICATIONS

1 Elderly individuals present with a vast array of body systems affected by the deranged physiology associated with aging. The physiology of aging affects nearly every organ system including cardiovascular, pulmonary, renal, and gastrointestinal. Altered physiology may also be associated with comorbid conditions in the elderly patient including hypertension, cardiac disease, chronic obstructive pulmonary disease (COPD), chronic renal insufficiency, and altered drug metabolism.

Cardiovascular

The cardiovascular system is most commonly affected by the physiology of aging and has a significant impact on care of the injured elderly patient. Alterations to physiology of the vascular system in the aging adult are primarily the result of changes in the large arteries including elongation, dilatation, and arterial wall thickening as a result of changes in the intima and media.² Changes in large arteries lead to decreased compliance, stiffness, and hypertension or other cardiovascular diseases in elderly adults. The aging process will affect cardiac physiology including reduced systolic and diastolic functions of the right ventricle as well as left ventricular hypertrophy with associated impaired contractility and relaxation. Resting cardiac output and ejection fraction are preserved.³ While there are significant changes in cardiac and vascular physiology in elderly patients at baseline, the lack of cardiovascular response to stress may be the most important component of altered cardiovascular physiology in elderly patients, especially in the setting of hemorrhagic shock. The blunted response to alpha-adrenergic stimulation limits vasoconstriction^{2,4} while lack of response to beta-adrenergic stimulation limits the ability to mount a tachycardic response.^{3,5} Elderly individuals are also at increased risk to develop atrial fibrillation, ischemic heart disease, and congestive heart failure.

Table 30-1 Changes in Cardiovascular and Pulmonary Physiology and Commonly Encountered Comorbidities in the Elderly

System Involved	Physiologic Changes	Common Comorbidity
Cardiovascular	Elongation, dilatation, and wall thickening of large arteries Decreased arterial compliance and stiffness Reduced systolic and diastolic function of right ventricle Left ventricular hypertrophy Lack of cardiovascular response	Hypertension Ischemic heart disease Atrial fibrillation Congestive heart failure
Pulmonary	Kyphosis Decreased intervertebral height Decreased muscular strength Loss of elasticity and recoil Emphysematous changes Dysfunction of mucociliary system Alterations in lung volumes, gas exchange, and respiratory drive Diminished physiologic response to hypoxia and hypercapnia	Chronic obstructive pulmonary disease (COPD) Asthma Obstructive sleep apnea

Pulmonary

The aging process also brings significant baseline anatomic and physiologic changes to the pulmonary system.⁶ The chest wall of the elderly individual changes over time with increasing kyphosis as well as decreasing height of intervertebral spaces. There is a decrease in strength of the intercostal muscles and diaphragm. After trauma, these anatomic changes place elderly patients at risk for earlier or more rapid respiratory failure as well as difficulty in liberation from the ventilator.⁶⁻⁸ In addition to alterations in the chest wall, there are several changes in the pulmonary parenchyma of elderly individuals. These changes lead to increased compliance due to loss of elasticity and elastic recoil, emphysematous changes, and dysfunction of the mucociliary system. While anatomic changes are important, the altered pulmonary physiology of aging may lead to significant clinical implications when caring for the injured elderly patient. The elderly individual will have changes to pulmonary physiology including alterations in lung volumes, gas exchange, and respiratory drive.⁶ Lung volumes in elderly patients will have increased residual volume and functional residual capacity but decreased vital capacity and FEV1.^{9,10} Alterations of pulmonary gas exchange in elderly patients include increased ventilation-perfusion mismatch as well as decreased diffusion across the alveolar-arterial membrane, both associated with a decrease in baseline PaO₂.^{11,12} Due to deranged respiratory drive seen with aging, elderly patients will

have a diminished physiologic response to both hypoxemia and hypercapnia.¹³ Some of the most common pulmonary comorbidities in the elderly trauma patients include COPD, asthma, and obstructive sleep apnea. [Table 30-1](#) displays changes in cardiovascular and pulmonary physiology as well as common comorbidities encountered in the elderly trauma patient.

Renal and Gastrointestinal

Aging causes deterioration in renal function over time due to alterations in renal vasculature, microanatomy, as well as changes in renal physiology.¹⁴ Elderly patients commonly have low-grade and/or undiagnosed chronic renal insufficiency putting them at risk for development of acute kidney injury after trauma. Avoiding nephrotoxic agents, intravenous contrast, hyperglycemia, and hypovolemia can help prevent acute kidney injury in elderly trauma patients. Gastrointestinal derangements in the elderly patient may include dysphagia, gastroesophageal reflux, gastroparesis, and diarrhea or constipation.¹⁵ In addition, many elderly trauma patients will present in a state of malnutrition established long before the time of injury. It is important to screen elderly trauma patients for nutritional status and begin enteral nutrition early in the postinjury course.

Elderly trauma patients present with a wide array of altered physiology and comorbid conditions. These pre-existing medical conditions are usually treated in the outpatient setting by primary care providers, and the mainstay of treatment is often a long list of medications. These preinjury medications can have a profound effect on the management and outcomes of elderly trauma patients. In addition, elderly individuals have an altered ability to metabolize the medications they encounter prior to injury as well as during their hospitalization.

Medications

Elderly trauma patients may be taking a variety of medications that may affect initial presentation, evaluation and treatment, and eventually outcomes. As hypertension is the most common comorbidity, elderly trauma patients will often be taking preinjury antihypertensive medications. Diuretics will cause patients to present in a hypovolemic state prior to injury or hemorrhage. Preinjury beta-blockers will blunt the tachycardic response and may confound the initial presentation.¹⁶ The most significant preinjury medications in elderly trauma patients are anticoagulants and antiplatelet agents. Elderly patients may be on anticoagulants or antiplatelet agents for a variety of conditions including atrial fibrillation, ischemic cardiac disease, valvular heart disease, cerebrovascular accidents, or thromboembolic disease. The most common outpatient anticoagulant is coumadin (vitamin K antagonist), but there have been several newer anticoagulants brought to market recently. These include the direct thrombin inhibitor dabigatran as well as the Xa inhibitors, rivaroxaban and apixaban. The most common antiplatelet agents include aspirin (cyclo-oxygenase inhibitor) and clopidogrel (ADP inhibitor). Newer antiplatelet agents include newer ADP inhibitors, prasugrel and ticagrelor.

Table 30-2 Common Preinjury Anticoagulants in the Elderly

Mechanism of Action	Drugs	Reversal Strategies
Vitamin K antagonist	Warfarin	FFP or PCC
Direct thrombin inhibitor	Dabigatran	Reversed with Idarucizumab (Praxbind) Intragastric charcoal Hemodialysis Consider PCC
Xa inhibitors	Rivaroxaban Apixaban	Reversal agent Andexanet alfa under investigation Intragastric charcoal Consider PCC
Antiplatelet agents	Aspirin Clopidogrel Prasugrel Ticagrelor	DDAVP Platelet transfusion

Reversal of anticoagulants and antiplatelet agents in elderly trauma patients can be a challenging and complex clinical scenario. The clinician must balance reversal to eliminate hemorrhage and thromboembolic complications associated with reversing anticoagulation or antiplatelet agents. Coumadin may be reversed with either fresh frozen plasma (FFP) or prothrombin complex concentrate

(PCC).^{17,18} There is limited evidence regarding reversal of direct thrombin inhibitors or Xa inhibitors.^{19–22} Dabigatran may be reversed with Idarucizumab (Praxnind). Intra-gastric activated charcoal may be administered if drug has been taken within 2 hours of presentation or hemodialysis may be considered. PCC may be considered for reversal of dabigatran but FFP is unlikely to have any therapeutic effect. Reversal agents for Xa inhibitors (Adnexasanet alfa) are currently under investigation. Activated charcoal may be used or PCC may also be considered. Antiplatelet agents may be reversed with either DDAVP or platelet transfusion, but the indications for either therapy have not been elucidated.^{21,23,24} Table 30-2 displays common preinjury anticoagulants and antiplatelet agents in the elderly trauma patient.

2 Once hospitalized, particular attention must be paid to medications ordered for the elderly trauma patient. Elderly patients have changes in pharmacokinetics and pharmacodynamics including alterations in absorption, bioavailability, distribution, metabolism, and elimination.²⁵ The American Geriatrics Society has published the Beers Criteria for potentially inappropriate medication use in older adults that can be used to refine inpatient medication management for elderly trauma patients.²⁶ Of particular importance to the management of the elderly trauma patients is the plan for pain control. Pain medications may have significant side effects in elderly patients including delirium, nausea, vomiting, constipation, renal dysfunction, and gastrointestinal bleeding. A multimodal approach with the lowest effective dose for pain control should be used for elderly trauma patients.²⁵

MECHANISM AND INJURIES

3 Mechanisms of injury for elderly trauma patients are most often a result of blunt trauma with falls, motor vehicle crashes, and pedestrian struck by auto being the most frequent. Falls are far and away the most common mechanism in elderly trauma patients, causing almost 75% of injuries.¹⁶ Fully, 90% of elderly falls are ground level falls. After hospitalization, older patients are at further risk for inpatient falls.²⁷ There are a variety of reasons that elderly individuals are at risk for falls including weakness, deconditioning from chronic illness, vision loss, gait and balance disturbances, slowed reaction time, and cognitive impairments.¹⁶ The American Geriatrics Society has developed clinical practice guidelines (Table 30-3) for the prevention of falls in older adults.²⁸

Elderly Abuse

4 An underreported but extremely important mechanism of injury in elderly trauma patients is abuse. Elderly abuse is committed by an individual who has a relationship with and is responsible for the well being of an elderly individual. Perpetrators of elderly abuse may include family members or care givers either in the home or at an assisted living facility. Abuse of the elderly is associated with depression, cognitive impairment, loss of functional capacity, and increased morbidity and mortality.²⁹ Several risk factors and warning signs for elderly abuse have been identified and are listed in Table 30-4.³⁰ If elderly trauma patients appear to be at risk for or display warning signs of possible abuse they may be assessed using a variety of available screening tools³⁰ including the American Medical Association (AMA) screening tool, the Conflict Tactics Scale (CTS), the Brief Abuse Screen for the Elderly (BASE), the Elder Assessment Instrument (EAI), or the Comprehensive Geriatric Assessment (CGA).

Traumatic Brain Injury

5 Traumatic brain injury (TBI) is a significant cause of morbidity and mortality in elderly trauma patients.^{31,32} TBI in elderly patients leads to almost 100,000 emergency department visits each year with the large majority requiring hospitalization. The most common mechanism causing TBI in elderly patients is falls (51%) followed by motor vehicle–related injuries (9%). All other causes combined make up 18% of TBI and about 20% are from an unknown cause. Imaging with head CT in elderly trauma patients should be used liberally for several reasons: (1) elderly patients have progressive brain atrophy leading to stretching of bridging veins and increased risk of subdural hemorrhage after trauma,³³ (2) clinical tools such as the New Orleans Criteria and Canadian CT Head Rule exclude elderly patients,^{34,35} and (3) neurologic examination may be unreliable in elderly trauma patients.^{36,37} The catastrophic combination of TBI and preinjury anticoagulation should prompt to rapid reversal of anticoagulation.^{38,39}

Fractures

Elderly patients have decreased cortical bone mass increasing their risk for fractures at lower levels of kinetic energy. As a consequence, older patients have increased risk of rib, spinal, pelvic, and extremity fractures after falls and other low impact mechanisms than younger patients.

Rib fractures are a significant cause of morbidity and mortality among older patients.⁴⁰ Retrospective studies show that in-hospital mortality for patients >65 years is double that of younger patients.^{41,42} The risk of mortality and pneumonia increases with increasing number of ribs fractured, and patients with more than three fractures have worse outcomes.^{41,43} Up to a third of older patients with rib fractures develop pneumonia and rib fractures are associated with mechanical ventilation and ICU length of stay.⁴¹

Osteoporosis, prior fracture, and functional impairment are all risk factors for pelvic fracture.⁴⁴ Over 80% of pelvic fractures are caused by falls, and morbidity and mortality after pelvic fractures is significant. In-hospital mortality approaches 8% and is up to five times higher than for younger patients.⁴⁵ Many patients after pelvic fracture require a cane or a walker, up to one-third are institutionalized, and 27% will die within a year of injury.⁴⁴

Table 30-3 AGS/BGS Clinical Practice Guideline: *Prevention of Falls in Older Persons*

Summary of Recommendations
Screening and Assessment 1. All older individuals should be asked whether they have fallen (in the past year). 2. An older person who reports a fall should be asked about the frequency and circumstances of the fall(s). 3. Older individuals should be asked if they experience difficulties with walking or balance. 4. Older persons who present for medical attention because of a fall, report recurrent falls in the past year, or report difficulties in walking or balance (with or without activity curtailment) should have a multifactorial fall risk assessment. 5. Older persons presenting with a single fall should be evaluated for gait and balance. 6. Older persons who have fallen should have an assessment of gait and balance using one of the available evaluations. 7. Older persons who cannot perform or perform poorly on a standardized gait and balance test should be given a multifactorial fall risk assessment. 8. Older persons who have difficulty or demonstrate unsteadiness during the evaluation of gait and balance require a multifactorial fall risk assessment. 9. Older persons reporting only a single fall and reporting or demonstrating no difficulty or unsteadiness during the evaluation of gait and balance do not require a fall risk assessment. 10. The multifactorial fall risk assessment should be performed by a clinician (or clinicians) with appropriate skills and training. 11. The multifactorial fall risk assessment should include the following:

Focused History
a. History of falls: detailed description of the circumstances of the fall(s), frequency, symptoms at time of fall, injuries, and other consequences
b. Medication review: all prescribed and over-the-counter medications with dosages
c. History of relevant risk factors: acute or chronic medical problems (e.g., osteoporosis, urinary incontinence, cardiovascular disease)
Physical Examinations
a. Detailed assessment of gait, balance, and mobility levels and lower extremity joint function
b. Neurologic function: cognitive evaluation, lower extremity peripheral nerves, proprioception, reflexes, and tests of cortical, extrapyramidal, and cerebellar function
c. Muscle strength (lower extremities)
d. Cardiovascular status: heart rate and rhythm, postural pulse, blood pressure, and, if appropriate, heart rate and blood pressure responses to carotid sinus stimulation
e. Assessment of visual acuity
f. Examination of the feet and footwear
Functional Assessment
a. Assessment of activities of daily living (ADL) skills including use of adaptive equipment and mobility aids, as appropriate
b. Assessment of the individual's perceived functional ability and fear related to falling (assessment of current activity levels with attention to the extent to which concerns about falling are protective [i.e., appropriate given abilities] or contributing to deconditioning and/or compromised quality of life [i.e., individual is curtailing involvement in activities he or she is safely able to perform due to fear of falling])
Environmental Assessment
a. Environmental assessment including home safety

Table 30-4 Risk Factors and Warning Signs for Elderly Abuse

History
Advanced age (>80 years)
Disability in self-care
Dementia
Depression
History of hip fracture
History of stroke
Social isolation
Poor socioeconomic status
External family stressors
Unfavorable caretaker characteristics (mental illness, substance abuse, history of violent or antisocial behavior, depression, or financial dependency on the victim)
Institutional staffing shortages
Inappropriate or excessive medications; failure to get needed medications; lack of appropriate monitoring of medications and their effects
Substance abuse
Physical/Mental Status Examination
Indicators of sexual abuse: pain, bruises, lacerations, bleeding in anal–genital areas; bruised breasts or abdomen; signs of venereal diseases
Lacerations (including large skin tears, abrasions, burns, and bruises) without adequate explanation, especially on the trunk or other unusual locations
Suspicious fractures in sites other than those seen in osteoporotic fractures, that is, wrist, hip or vertebral body
Malnutrition
Focal findings on neurologic examination
Signs of dehydration
Pressure ulcers
Dementia, psychiatric disorders, lack of mental capacity

Spinal trauma is increasingly common in elderly patients.⁴⁶ The risk of cervical fracture after falls increases with age due to higher rates of cervical stenosis and degenerative disk disease.⁴⁷ An estimated 5% to 10% will sustain spinal injury and permanent neurologic deficit after cervical fracture, and 1-year mortality is estimated to be 20% to 30%.⁴⁸

Fourteen percent of elderly patients who sustain hip fracture after falls die within 6 months and

almost one-fourth dies within a year.^{49,50} Most do not regain prior functional abilities, and patients after hip fracture are five times more likely to live in an institution a year after injury. Hip fracture in older patients often leads to depression,⁵¹ social isolation, and worse overall health. Up to half of patients with hip fracture experience pain for many months after injury.⁵² Shorter time to surgery is associated with decreased mortality and fewer complications.⁵³

TRIAGE CRITERIA FOR OLDER PATIENTS

6 Trauma center care reduces in-hospital mortality for older trauma patients,^{54,55} and the benefit of treatment at trauma centers for older patients increases with age.⁵⁶ However, triage of older patients can be quite challenging. Even severely injured older patients may not display standard signs of hemodynamic instability. Furthermore, because older patients cannot tolerate large blood loss and shock, some have advocated that systolic blood pressure ≤ 120 mm Hg should trigger trauma activation to prompt earlier intervention.⁵⁷ The Centers for Disease control suggest that injured patients >55 years should be transferred to a trauma center, regardless of injury severity.⁵⁸ The Eastern Association for Trauma (EAST) guidelines recommend that trauma centers should lower threshold for trauma team activation for elderly patients. Further, the guidelines suggest that older patients should be transferred to a level I center if they have a base deficit of -6 or greater, or one body system AIS is >3 .⁵⁹ In a retrospective study using the National Trauma Data Bank, Pandit et al.⁶⁰ showed that shock index (HR/SBP) >1 was associated with higher rates of blood transfusions, exploratory laparotomy, in-hospital complications, and in-hospital mortality. Based on these findings, the authors recommend that patients with a shock index >1 should be transferred to level I trauma centers.

Despite evidence supporting higher triage, multiple studies show that older patients are routinely undertriaged. Data from the Washington State database showed that the likelihood of being transferred to a trauma center decreased above age 45.⁶¹ Compared to younger patients in the cohort, patients 81 years and older were only 11% as likely to be transported to a level I trauma center from the scene, and only 24% as likely to be transferred from a lower level center to a level I center. The relationship between trauma center admission and longer-term outcome is controversial. One study of severely injured older patients (ISS >15) in three counties in California showed that older patients were less likely to receive care at trauma centers, yet mortality at 60 days after injury was no different.⁶²

EVALUATION AND MANAGEMENT

Comprehensive Geriatric Assessment

Older patients are much more likely to have medical comorbidities, extensive lists of medications and social needs that require special attention. A retrospective study of older trauma patients showed that 69% of patients age 75 to 79 years and 90% of those >80 years have comorbidities.⁶³ The most common are cardiopulmonary (coronary disease, hypertension, congestive heart failure, and COPD). Geriatric syndromes such as dementia and frailty also play important roles and are frequently the primary contributors in falls and motor vehicle crashes. Malnutrition, hearing loss, vision loss, incontinence, polypharmacy, and osteoporosis all increase the risk of falls; weakness from sarcopenia and sensory deficits also place elders at high risk for being either struck by motor vehicles, or driving in motor vehicle crashes. Alcohol and substance abuse are under-recognized contributors to injury in geriatric trauma patients.⁶⁴

7 Due to the broad range of age-related factors that can contribute to injury and adversely affect recovery in geriatric patients, patients should receive a comprehensive geriatric assessment (CGA) during their hospital stay. This is a multidimensional and multidisciplinary evaluation including functional ability, physical health, cognition and mental health, and medication review. A recent meta-analysis of 22 randomized trials showed that hospitalized elders who receive a CGA are less likely to die in hospital, have higher rates of discharge home, and improved long-term functional outcomes.⁶⁵ Functional status is evaluated with a review of activities of daily living (ADL) (eating, dressing, bathing, transfers, toileting, continence) and instrumental ADL (housework, bills, meal preparation, medication management, using the telephone).⁶⁶ Physical and occupational therapists can assess gait, balance, home safety, and ability to carry out ADL.

Medications commonly used in older patients can exacerbate injury. Postural hypotension is a

common condition in older adults, leading to falls, and can be caused by medication side effects (diuretics, antiarrhythmics, benzodiazepines, antidepressants, and psychotropic agents).^{67,68} Antidepressants and psychotropic agents can cause gait impairment. Most patients should receive a nutritional assessment because malnutrition in elderly patients is highly prevalent; 38% of community-dwelling elders are either malnourished or at risk of malnourishment.⁶⁹ Social workers can assess social supports, caregiver needs, financial assets and identify resources for the patient and family after hospital discharge. Poverty rates are highest for those 85 and older, and rates are increasing.⁷⁰ Social isolation is also a major contributor to poor health in this age group.⁷¹ Those without social support have more frequent hospitalizations and higher healthcare costs near the end-of-life.⁷² They are also more likely to be discharged to institutions. In cases where it is impractical to thoroughly evaluate each condition during hospitalization, patients should be referred for outpatient follow-up at discharge.

Assessing Frailty

8 Frailty is a syndrome of decreased physiologic reserve distinct from the normal aging process and other comorbidities. Frailty is associated with higher mortality and complications, and worse functional outcomes after trauma, and is more predictive than age or injury severity as a predictor of hospital complications, in-hospital mortality, or discharge to an institution.⁷³ The prevalence of frailty increases with age: 7% of 65 year olds are frail whereas 30% of patients 80 and older are frail.⁷⁴ Components of the frailty syndrome include shrinkage, weakness, exhaustion, low physical activity, and slowness. Presence of three or more of these indicates frailty.⁷⁵ Multimorbidity and side effects from certain medications may exacerbate frailty.

Screening for frailty identifies patients at risk for adverse outcomes, but frailty remains difficult to quantify. Frailty can be assessed using a number of different measures.⁷⁶ Investigators at the University of Arizona recently developed a frailty index using 50 preadmission variables that included data about demographics, comorbidities, medications, social history, ADLs, and mood. A frailty index was calculated based on the proportion of the 50 variables that were present; high score was indicative of frailty. These investigators demonstrated that after adjusting for age injury severity score and Glasgow coma score, higher frailty index predicted increased odds of unfavorable discharge (death or skilled nursing facility).^{73,77} Other investigators have considered sarcopenia, a loss of muscle leading to decreased strength and impaired mobility, as a surrogate measure of frailty in trauma patients. Sarcopenia is associated with more days on the ventilator, and higher postacute care needs.⁷⁸ Sarcopenia can be measured using the cross-sectional area of the psoas muscle on abdominal CT, a measure which is inversely related to functional dependence.⁷⁹ The Vulnerable Elders-13 Survey, an assessment of functional status, has been validated as a screening tool to predict discharge to nursing facility, and surgical complication or death in trauma patients 65 years or older. In a prospective study of 63 geriatric trauma patients, each VES-13 point increased the odds of complication by 1.53.⁸⁰

Patient Management

Data are emerging that unique expertise, and specialized pathways and processes of care improve outcomes in injured geriatric patients. A retrospective study of the Pennsylvania State database found that trauma centers with the highest volume of geriatric patients, rather than the highest overall trauma volume, had lower mortality, fewer complications, and lower rates of failure-to-rescue, suggesting that experience with older patients at the center level improves outcome.⁸¹ A recent meta-analysis in hip fracture patients showed that routine geriatric consultation, comanagement, or geriatric admission with orthopedic consultation reduced in-hospital mortality by 40% and longer-term mortality by 17%.⁸² Among trauma patients, triggered or proactive, geriatric consultation is associated with lower rates of delirium, fewer consults to medicine and psychiatry, and fewer discharges to facilities among patients who were admitted from home.⁸³ In another pre-post study of routine geriatric consult in trauma patients over 65 years, Tillou et al.⁸⁴ showed that patients who received a geriatric consultation had better functional recovery at 6 and 12 months after injury than patients without the consultation.

Some centers have reported success in developing clinical pathways for geriatric trauma patients. Bradburn et al.⁸⁵ implemented a high-risk geriatric protocol at their level II trauma center. As part of the protocol, patients received arterial blood gas determination at the time of trauma activation, were admitted to the ICU, and received a geriatric consultation. If the initial base deficit was >6 , it was rechecked every 4 hours until normalized. Patients treated under the protocol had 40% lower mortality than those who did not receive the protocol. Bar-Or et al.⁸⁶ also showed improved mortality among trauma patients >65 years who routinely received serial venous lactate measurement and early surgical

consultation. Mangram et al.⁸⁷ created the dedicated G-60 unit at their level II trauma center for trauma patients over 60 years who were admitted within 48 hours of injury. Patients were evaluated by a surgeon and a hospitalist at the time of trauma activation, and admitted to the surgical service. Other services including physical medicine and rehabilitation, palliative care, physical and occupational therapy, respiratory therapy, the G-60 nurse supervisor, social work, nutrition, pharmacy were also notified at the time of activation and evaluated patients within 24 hours of admission. Surgeon-led multidisciplinary rounds occurred twice weekly. As compared to historical controls, patients on the G-60 service had significantly shorter ED length of stay, time to OR, hospital length of stay, and ICU length of stay. Although mortality was unchanged, there were also significantly lower rates of medical complications.

OUTCOMES

Mortality Outcomes

The relationship between age and adverse outcomes among older trauma patients is well recognized.⁸⁸ As compared to younger patients, in-hospital mortality for older patients are 4.4% versus 1.6% for low severity injuries and 5.9% versus 1.4% for moderate severity injuries. Moreover, mortality among older trauma patients increases with the number of comorbidities; patients with minor injuries and comorbidities are at increased risk of death compared to age-matched counterparts without comorbidities.⁸⁹ It is important for clinicians to recognize that significant numbers of geriatric trauma patients die shortly after hospital discharge, and patients have higher mortality than age-matched counterparts for years after injury. Clark et al.⁹⁰ showed that mortality at 30 days was nearly double the in-hospital mortality. Fleischman et al.⁹¹ found that 89% of postinjury mortality occurs by 60 days and that mortality rates level off at 6 months. Davidson et al.⁹² found that while all trauma patients had higher mortality up to 3 years after injury than age-matched controls, older patients and those discharged to skilled nursing facilities fared particularly poorly.

Functional Outcomes

Most older trauma patients will return to their prior level of function, and thus an initial aggressive approach to treatment in a trauma center is warranted.⁵⁹ A significant portion experiences long-term functional decline after injury. A follow-up study of blunt trauma patients showed that 87% were functionally independent 1 to 3 years after injury, and another with mean follow-up 2.8 years after injury showed that 63% remained independent but with reduced function.⁹³ Studies with 12 months or less follow-up show higher rates of decreased functional abilities. In a prospective study of 37 patients > 65 years, Kelley-Quon et al.⁹⁴ showed that most patients had lost 1 ADL at 12 months. More recent data from this group show that a geriatric consultation during the index hospitalization is associated with less long-term functional decline.⁸⁴ Quality of life in older patients is significantly impaired. Among patients 1 year after hip fracture 90% have reduced mobility, 69% have pain, and 33% who were independent live in a nursing home. As compared to patients without TBI, a cohort of patients > 50 years old had poorer cognitive and psychosocial function a year post injury.

PALLIATIVE AND END-OF-LIFE CARE IN THE GERIATRIC TRAUMA PATIENT

9 Palliative care is an approach to medical care aimed at relieving suffering and improving quality of life for patients with serious illness and for their families. Palliative care is appropriate in the management in a broad range of injured patients who die or suffer with acute and chronic pain, functional disability, or life-limiting conditions such as severe frailty and underlying organ failure.⁹⁵ Clinical domains of palliative care encompass symptom management. Spiritual, religious, psychosocial, and bereavement support can be delivered alongside aggressive life prolonging care and should not be limited to only those patients near the end-of-life.⁹⁶ Thus palliative care can be provided to patients who are “cured” of their illnesses or recover from injury. Palliative care should not be confused with hospice care which is an administrative benefit provided to patients with terminal illness and typically provided to patients expected to survive less than 6 months.

End-of-Life Care

10 Four-fifths of in-hospital deaths among geriatric trauma patients involve decisions to withdraw or withhold of life-sustaining therapies.⁹⁷ Advanced directives, including living wills and proxy forms are intended to guide medical decisions in the event a patient loses capacity to make decisions. Unfortunately, many patients, even those with terminal illness, do not have advanced directives or the advanced directives are too specific or too broad to be useful.⁹⁸ Therefore, it is critically important that clinicians make every effort to engage patients and their families in conversations about the overall goals of care and expectations for recovery. Patients may forego heroic measures and prolonged life-sustaining treatments if all possible outcomes are not acceptable to them.⁹⁹ It is advisable for clinicians to identify healthcare proxies and address code status early in the hospital stay and ideally with the patient.

Physicians play an important role in providing a comfortable death experience for patients and families. In death, patients want to minimize discomfort, to avoid a prolonged dying process, to achieve a sense of control, and time to strengthen relationships with loved ones.¹⁰⁰ Survivors and surrogates suffer high rates of depression, posttraumatic stress disorder, and complicated grief after a loved one dies in the ICU.¹⁰¹ Better outcomes for survivors are achieved when they feel that they have been well informed and had appropriate responsibility in decision-making.¹⁰² It is important for physicians to provide emotional support for surrogates who are often conflicted and distressed.

In cases where the primary goal is comfort, liberal use of opioids can reduce pain and dyspnea. Some clinicians may be reluctant to use opioids for fear of causing respiratory depression and death. Opioid use is ethically justifiable in these scenarios as long as the intent is symptom relief and not euthanasia. Patients should receive doses adequate to achieve comfort; target respiratory rate is 15 to 20 breaths per minute. When patients die, physicians should be available to answer questions and address bereavement needs. The way death is communicated is important. In a study of survivors of patients who died in the ICU, failure to find the physician comforting was most strongly associated with developing a psychiatric diagnosis in the year after death.¹⁰¹ In another study of 70 survivors of cancer patients, feeling unprepared was a predictor of major depressive disorder up to 9 months.¹⁰³

Hospice

Hospice is an interdisciplinary approach to care that provides comprehensive, medical, nursing, counseling, and bereavement to terminally ill patients and their families. Referral for hospice care is appropriate when patients have a limited prognosis and the primary goal is comfort and symptom management. In the care of geriatric trauma patients, hospice may be relevant to patients with severe TBI or patients who sustain injury in the setting of other advanced serious underlying illnesses with life expectancy 6 months or less. Hospice care is associated with better quality of life, better bereavement outcomes, lower healthcare costs, and either equivalent or improved survival in patients with a terminal diagnosis.^{104–107} The impact of transition to hospice on trauma center mortality reporting is unclear. Kozar et al. found wide variation among 167 trauma centers enrolled in the Trauma Quality Improvement Project as to whether they reported patients discharged to hospice as in-hospital deaths or survivors. The authors advised that hospice discharge should be considered death across centers to prevent distortion of actual performances.¹⁰⁸

Chapter 31

Trauma in Pregnancy

Felix Y. Lui and Kimberly A. Davis

Key Points

- 1 Unique challenges exist in the management of the pregnant patient that need to be addressed in order to achieve optimal outcomes for both the mother and child.
 - 2 Anatomic and physiologic changes in the maternal trauma patient evolve over the course of pregnancy and require modifications in management based on gestational age.
 - 3 Patient care should be tailored for the anatomic and physiologic changes in the gravid trauma patient, but priorities remain the same as for the nongravid patient.
 - 4 Relative hypervolemia of pregnancy can mask large-volume hemorrhagic losses and requires rapid identification and aggressive resuscitation.
 - 5 Compression of the inferior vena cava (IVC) and decreased cardiac output can result from supine positioning. Proper positioning and use of a wedge is recommended.
 - 6 A Kleihauer–Betke test should be performed in all pregnant trauma patients with greater than 12 weeks of gestation and prophylactic anti-D immune globulin given within 72 hours for high-risk patients.
 - 7 Radiation exposure should be minimized in all pregnant trauma patients. Ultrasound (including FAST) exposes the mother and fetus to no radiation and is reliable, has good negative predictive value, and can be followed serially over time.
 - 8 Angiography and angioembolization may be useful in life-threatening hemorrhage, recognizing the risks of increased radiation exposure.
 - 9 Pregnant patients are at an increased risk for deep venous thrombosis (DVT) and should be given unfractionated subcutaneous heparin for prophylaxis.
 - 10 Providers should have a low threshold for screening maternal trauma patients for intimate partner violence (IPV) and substance abuse.
-

INTRODUCTION

Trauma is the leading cause of nonobstetric death in pregnant patients worldwide. As the risk of death due to pregnancy-related complications has declined, trauma now accounts for nearly half of maternal deaths in the United States annually, with an up to fourfold increase in fetal mortality in some series.^{1,2} Pregnant trauma patients have increased rates of preterm labor and placental abruption, and their infants are at increased risk of respiratory distress and fetal death.³

The trauma evaluation of the pregnant patient presents unique challenges including alterations in anatomy and physiology that evolve continuously throughout pregnancy, pregnancy-specific patterns of injury, and pregnancy-specific challenges in critical care and surgical management.

Pregnant patients also present special social and ethical issues in trauma. Interpersonal violence against the pregnant female is an underrecognized phenomenon worldwide and has long-lasting effects on both mother and child. While management of the pregnant trauma patient focuses on the resuscitation of the mother, consideration of fetal survival and outcome must be considered in the management of these patients.

1 Trauma in the pregnant patient presents as a unique situation in which treatment is required in two (or more) patients simultaneously. In order to provide the optimal level of care to both the mother and child, the practitioner needs to recognize the unique anatomical and physiologic changes of the gravid patient as the pregnancy progresses, and how they alter the treatment of these patients.

EPIDEMIOLOGY OF INJURY DURING PREGNANCY

Up to 37% to 46.3% of gravid maternal deaths in the United States are attributable to trauma, resulting in over one million deaths annually worldwide. An estimated 5% to 7% of pregnancies are complicated by trauma, and 0.3% to 0.4% of all pregnant females required hospitalization for treatment of injuries.⁴⁻⁷ The majority of trauma occurs later in pregnancy, with greater than 50% occurring during the third trimester. Motor vehicle–related injuries are the most common cause of trauma and injury (up to 33.6%), followed by falls and interpersonal violence.⁸ Although motor vehicle collisions are no more common in pregnancy, they remain the leading cause of fetal death due to frequency of maternal trauma.^{9,10} Fetal death occurs in up to 50% of life-threatening traumatic injury to the mother, but due to the frequency of minor trauma, the majority of fetal loss occurs after minor traumatic injuries.¹¹ Violence due to domestic abuse is an underrecognized cause of maternal and fetal injury and death. Interpersonal violence between intimate partners occurs in up to 30% of pregnant women, with a fetal mortality of 5%. While most common in first 18 weeks of gestation, violence is prevalent throughout gestation. The risk of IPV is greatest immediately after delivery of a child.¹²⁻¹⁴

PATTERNS OF INJURY

2 The development of the fetus and enlargement of the uterus throughout pregnancy affects the patterns of injury experienced depending on stage of development. Until the 12th week of gestation, the uterus is thick walled and is well protected by the surrounding pelvis. By the 20th week of gestation, the uterus extends out of the true pelvis up to the umbilicus and by the 34th week, the costal margins. As the uterus grows, the protection conferred by the bony pelvis is lost and the fetus becomes increasingly vulnerable to direct trauma and injury. Later in pregnancy the relative thickness of the uterine wall decreases, as does the relative volume of amniotic fluid surrounding the fetus, further limiting the protective barrier surrounding the fetus and predisposing the uterus to shear forces and rupture.

Motor vehicle collisions remain the most common mechanism of significant blunt trauma in the pregnant patient. Maternal seatbelt use is associated with improved outcomes and decreased fetal mortality.¹⁵ As the growing uterus emerges out of the pelvis after the 12th week of gestation, the fetus is increasingly exposed to direct blunt trauma by seat belt or steering wheel injuries. Trauma to the fetus commonly results in skull fracture or intracranial hemorrhage, especially late in pregnancy. Placental abruption, resulting from shear of the relatively inelastic placenta against the flexible uterine wall, is the most common cause of fetal demise from trauma. Uterine rupture is fortunately rare, but carries a rate of fetal demise near 100% and maternal mortality of 10%. Pelvic fractures are a sign of high-energy forces and can result in severe retroperitoneal hemorrhage of the mother with hypotension, and severe direct injury to the fetal head as it descends into the pelvic inlet late in pregnancy.

Penetrating trauma to the pregnant patient carries a high rate of fetal mortality, ranging from 40% to 80%, depending on mechanism, gestational age, and location.¹⁶⁻¹⁸ Up to 9.5% of trauma in pregnant patients is intentional, with 73% of penetrating abdominal wounds in pregnancy resulting from gunshot wounds.¹⁷ Gunshot wounds to the abdomen mandate exploratory laparotomy, whereas stab wounds may be managed selectively depending on the presence or absence of fascial disruption.¹⁹ Fetal injury occurs in 70% of gunshot wounds to the pregnant abdomen. Diagnostic peritoneal lavage may be useful in evaluating these patients, though focused abdominal sonography for trauma (FAST) has largely supplanted its use. FAST ultrasound in the pregnant patient has a sensitivity of 61% to 83% and a specificity of 94% to 100% in detecting intraperitoneal injuries.²⁰⁻²² Direct trauma to the uterus can be associated with large-volume blood loss due to the engorged uterine vessels.

EVALUATION OF THE PREGNANT TRAUMA PATIENT

3 The evaluation of the pregnant trauma patient follows the same principles as for the nonpregnant patient as outlined in the American College of Surgeons' Advanced Trauma Life Support guidelines.²³ The evaluation and resuscitation begins with the primary survey, utilizing a systematic ABCDE approach, and followed by a complete assessment of injuries in the secondary survey. Basic tenets of surgical intervention and “damage control” techniques should be followed. The best outcomes for the fetus are achieved by the optimal evaluation, resuscitation, and treatment of the mother.

Chart 31-1 Frequency of Injury in Fetal Trauma Deaths

Injury Pattern	Frequency
Placental abruption	20%
Excessive bleeding	3.3%
Breech/malpresentation	2.1%
Placenta previa	0.8%

The main priorities in prehospital care continue to be the avoidance of hypoxia and hypotension in the mother. Maintenance of an adequate airway, as well as provision of supplemental oxygen, is essential in avoiding fetal hypoxia. Circulatory support with crystalloids is recommended and should be initiated early. The relative hypervolemic state of pregnancy means that a large-volume blood loss can occur prior to the development of signs of shock. Displacement of the uterus off the inferior vena cava (IVC) or tilting of the patient with a wedge may be required to augment cardiac return. A detailed obstetric history including length of gestation, prenatal care, complications, and names of care providers can be valuable information for the trauma team.

During the trauma evaluation, the priorities in patient management remain the same in the pregnant patient as in the nonpregnant patient. Adequate oxygenation of the mother, by ensuring an adequate maternal airway with supplemental oxygen, best ensures the adequate oxygenation of the fetus. Access for resuscitation can be achieved with peripheral IVs or subclavian or jugular venous central access. Blood loss should be treated with crystalloid and blood transfusion following the principles of damage control and balanced resuscitation, with an emphasis on early use of blood and blood products in the event of life-threatening hemorrhage.^{24,25}

In the secondary survey, a complete physical examination is essential. In addition to a complete examination for maternal injuries, complete examination of the fetus includes estimation of uterine size and fundal height, examination for vaginal bleeding, rupture of membranes, presence of bulging perineum, contractions, or abnormal fetal heart rate (FHR) or rhythm. Vaginal bleeding may be an indicator of premature cervical dilation, early labor, abruption placentae, or placenta previa. Cloudy white or green fluid from the cervical os may represent amniotic sac rupture. A vaginal speculum examination should be performed to assess for cervical dilatation and bleeding from the cervical os. Strong contractions, or bulging of the perineum (due to the presenting part of the fetus) can signal imminent delivery (or abortion in early pregnancy).

A thorough medical and obstetric history is required for all patients in whom it can be obtained. An accurate date of last menstrual period and expected delivery aids in measurement of uterine size, height, and position. A history of complications of the present or previous births, such as hypertension, preterm labor, abruption placentae, or placenta previa aids in evaluation and management, due to the high rate of recurrence.

Options for evaluation of the fetus include Doppler FHR monitoring or ultrasound. Normal FHR ranges from 120 to 160 beats/min. Tachycardia (>160 beats/min) is seen during stress, hypoxia, or hypotension, however bradycardia (<120 beats/min) also indicates fetal distress and mandates immediate maternal resuscitative efforts including supplemental oxygen, fluid, or blood administration. Fetal heart monitoring should be performed in all potentially viable fetuses involved in a traumatic abdominal injury.

Airway

Increased metabolic needs of the mother and fetus lead to a 30% to 60% increase in oxygen consumption. This in combination with decreases in functional expiratory reserve volume and functional residual capacity due to the enlarged uterus and upward pressure on the maternal diaphragms leads to decreased overall respiratory reserve and can result in rapid onset of hypoxia of mother and fetus.

The average pregnant patient gains about 17% of body weight during pregnancy.²⁶ This results in an overall increase in BMI from fat and protein deposition, blood volume, interstitial fluid, and uterine size. The resulting increase in Mallanpati scores may complicate airway management and result in morbidity due to failed intubations.²⁷ Raised progesterone levels also increase total-body water and result in generalized edema, including edema of the airway. Edema of the tongue, oropharynx, and trachea may impair visualization and intubation of the airway, further complicating intubation. These changes progressively increase with increasing gestational age.²⁸ Gastric compression due to increased fundal height and lower esophageal sphincter dysmotility contribute to an increased risk of aspiration and early intubation should be considered for at-risk patients. Preoxygenation, cricoid pressure, and

avoidance of bag-mask ventilation when possible are recommended.

Cardiovascular System

4 Beginning at 10 weeks of gestation, intravascular blood volume increases steadily over the course of pregnancy, reaching up to 50% above normal by term.²⁹ The increase in plasma volume is relatively greater than the approximately 15% increase in red blood cell (RBC) mass initially; therefore a relative physiologic anemia is seen during early pregnancy. However, erythrocyte production increases later in pregnancy, and after a nadir at 30 to 32 weeks, hematocrits are near normal by term. The relative hypervolemia of pregnancy can mask large-volume hemorrhagic losses and up to 35% of maternal blood loss can be lost prior to signs and symptoms of shock. Pulse rates increase by 10 to 15 beats/min and remain elevated until delivery.

5 As the gravid uterus increases in size, supine positioning can result in “supine hypotensive syndrome” resulting in compression of the IVC and decreased blood return to the heart, resulting in up to a 30% decrease in cardiac output. Symptoms include lightheadedness, dizziness, pallor, tachycardia, and hypotension. Displacing the uterus laterally to the left of the patient, either manually or by use of a wedge to tilt the patient >15 degrees to the patient’s left can restore perfusion.

Fluid resuscitation is the first-line therapy for the unstable pregnant trauma patient. Catecholamine release preserves the maternal blood pressure through maternal peripheral vasoconstriction, but decreases fetal blood flow via placental vasoconstriction. Adequate access is essential in the injured pregnant patient, as decreased fetal blood flow precedes maternal hypotension.³⁰ Two large bore intravenous lines, preferably above the diaphragm, should be placed initially. Adjustments must be made for the relative hypervolemia of pregnancy and fetal distress can precede maternal instability. Blood and blood product transfusion should be considered early in the unstable trauma patient. Type O, Rh-negative blood should be used until type specific or cross-matched blood is available. In the resuscitated, euvoletic patient, if pressor support is required, ephedrine and phenylephrine have the least effect on uterine-placental vasculature and are recommended for initial pressor support in pregnant patients. Additional pressors such as norepinephrine and epinephrine can be considered in the unstable patient, especially in those without a viable pregnancy.³¹

Compression of the IVC by the gravid uterus decreases venous return to the heart and can decrease cardiac output by up to 30%. During cardiopulmonary resuscitation (CPR), lateral displacement of the uterus to the patient’s left can improve hemodynamics and CPR efforts. In late pregnancy (>24 weeks), use of a foam wedge or padding to tilt the patient up to 30 degrees to her left can be helpful, though CPR is only 80% effective in this position. Standard Advanced Cardiac Life Support (ACLS) voltage should be used if defibrillation is required.

Pulmonary System

Increased intra-abdominal pressure from the growing uterus causes elevation of the diaphragm and results in a decrease in total lung capacity and functional residual capacity. This results in a compensatory chronic hyperventilation with 30% to 40% increase in minute ventilation. The resultant chronic respiratory alkalosis facilitates transfer of fetal CO₂ to the maternal circulation. Overaggressive correction of respiratory acidosis in the mother can have deleterious effects on the fetus.³² Hypocapnia (PaCO₂ of <30 mm Hg) is common in pregnancy and a “normal” CO₂ (~40 mm Hg) may be a sign of imminent respiratory failure. Oxygen consumption is increased approximately 20% in pregnancy and needs to be accounted for in oxygen supplementation.

Elevation of the diaphragm late in pregnancy requires care to be taken when thoracostomy tube placement or thoracentesis is required. Chest tubes for hemo- or pneumothoraces require higher placement and should be inserted in the third or fourth intercostal space.

Ventilatory support, when required, should be individualized to optimize oxygenation and avoid acidosis. There are no studies addressing the ideal way to manage ventilatory support in pregnant patients with acute lung injury or ARDS. While lung protective strategies may be beneficial, hypercapnea in these patients should be avoided.

Gastrointestinal System

The growing uterus causes progressive gastric compression as the pregnancy progresses. Increased progesterone levels in pregnancy result in decreased function and tone of the lower esophageal sphincter, as well as decreases in gastric tone and motility. This places the mother at increased risk of

aspiration, especially during intubation. During intubation, rapid sequence induction is recommended given the high risk of aspiration. High levels of progesterone decrease gallbladder contractions and lead to bile stasis and formation of gallstones.

Genitourinary System

Renal function increases to meet the demands of increased circulatory volume during pregnancy. Renal blood flow and glomerular filtration rates (GFRs) increase by 50% to 60% and levels of blood urea nitrogen (BUN), creatinine, urate, and bicarbonate are decreased. Increased water retention causes decreased plasma osmolality. Relaxation of the bladder smooth muscle increases capacity, stasis, and the risk of development of urinary tract infections and pyelonephritis.^{33,34}

Hematologic System

Increased intravascular volume relative to RBC production leads to a physiologic anemia with an average hematocrit of 32 during the first two trimesters. This corrects to near normal hematocrit levels by term. White blood cell counts (WBCs) also are relatively increased and can range from 9,800 to 15,000/mm³.

Increased estrogen levels lead to increased production of factors VII, VIII, IX, X, and XII and plasma fibrinogen levels are elevated about 30% to 50%. Plasminogen activator levels are decreased. Protein S activity is decreased and protein C activity is increased.³⁵ This leads to the “hypercoagulable” state of pregnancy and places these patients at increased risk of deep venous thrombosis (DVT) and pulmonary embolism (PE), with slower resolution and lysis of clot. Normal levels of coagulation factors should raise the suspicion of disseminated intravascular coagulation (DIC).

6 During trauma, entry of fetal Rh+ blood (as little as 0.07 mL) into the blood stream of an Rh– mother results in formation of antibodies. These antibodies, while harmless to the mother, can reenter the bloodstream of the fetus (or subsequent pregnancies) and cause hemolysis of the fetal RBCs. Prophylactic anti-D immune globulin (RhoGAM™) should be given within 72 hours of trauma when significant risk of maternofetal hemorrhage exists. A Kleihauer–Betke (KB) analysis should be performed for all pregnant patients with >12 weeks of gestation.^{36,37} A study out of University of Maryland showed a positive KB was the single predictive risk factor for preterm labor with a likelihood ratio of 20.8.³⁸

Chart 31-2 Frequency of Injury by Mechanism

Mechanism	Frequency
Motor vehicle collision (MVC)	48.6%
Falls	25.4%
Assault	17.5%
Gunshot	4.3%
Suicide	3.4%
Burns	0.7%

MONITORING AND EVALUATION OF THE FETUS

Pregnancies beyond 24 weeks of gestation are considered viable, and an expedient estimation of gestational age is required. Patient history, fundal height, or ultrasonographic measurement of femur length (in the third trimester) or biparietal measurements can be used.

Optimal management of the pregnant mother results in the best chance of survival of the fetus. However, studies showing fetal death rates can be several fold greater than maternal deaths rates in trauma suggest that maternal survival in itself is not sufficient. Close monitoring of the viable fetus is necessary. Continuous fetal monitoring is the only way to identify fetal distress in the acute setting.³⁹ The Eastern Association of Surgery for Trauma (EAST) guidelines recommend monitoring of all pregnant female with gestation >20 weeks for at least 6 hours after significant trauma.⁴⁰ Early involvement of the neonatal intensive care staff is recommended.

RADIOGRAPHIC IMAGING IN TRAUMA

The ideal diagnostic imaging test in the pregnant patient should be fast, readily available, safe, and accurate. Selection of the appropriate test needs to balance the need for expedient diagnosis while minimizing risk to mother and fetus. During pregnancy, radiation exposure should be avoided or minimized whenever possible. Exposure to less than 5 rad of radiation has not been associated with fetal anomalies or pregnancy loss, and is safe at any gestation age.⁴¹ With proper shielding, however, minimal radiation is transmitted to the fetus with plain films (Chart 31-4).

7 Sonographic evaluation of both the mother and fetus is safe and useful in determining the extent of injuries. FAST ultrasound has excellent specificity and negative predictive value in detecting pericardial, pleural, and peritoneal free fluid in the hemodynamically unstable mother and poses no risk to the fetus.⁴² Ultrasound is particularly useful in the evaluation of intrauterine contents, but can miss 50% to 80% of placental abruptions.⁴³ Fetal ultrasound should be performed to assess for gestational age, cardiac activity, and movement.

CT scans are rapid and sensitive for evaluation of traumatic injuries. CT scans of the head and neck can be performed with minimal radiation exposure to the fetus. As radiation exposure levels from CT scans of the chest, abdomen, and pelvis can be variable, the use of CT should be minimized whenever possible. However, CT imaging should be performed when appropriate for complete evaluation of traumatic injuries. Practitioners should utilize radiation reduction strategies whenever possible.⁴⁴

Magnetic resonance imaging (MRI) poses minimal risk to the fetus and may have a role in the evaluation for ligamentous injuries of the spine and spinal cord injuries. However, use of this modality is limited due to availability and length of time required to perform. Additionally, the MRI scanner is often remote from the resuscitation area, and ongoing resuscitative efforts may not be feasible when the patient is undergoing MRI. Therefore, MRI should only be utilized in hemodynamically normal patients without ongoing resuscitation requirements.

8 Angiography and angioembolization may be useful in the event of life-threatening hemorrhage, but radiation dose increases with increasing duration and extent of evaluation. Typical exposure ranges from 2 to 10 rad/min, and the risk versus benefit needs to be carefully weighed, and patients appropriately counseled. Embolization of the gravid uterus is not recommended, however embolization of the nonuterine vessels is feasible and can be life-saving in pelvic fractures with ongoing hemorrhage.⁴⁰

In counseling patients and families, healthcare providers should emphasize that the radiation exposure from a single diagnostic test is not sufficient to cause harmful effects to the fetus, and that concerns regarding possible effects of radiation should not prevent the use of medically indicated diagnostic studies.⁴⁵

SPECIAL CONSIDERATIONS

Pelvic Fractures

Pelvic fractures in pregnancy are associated with a high rate of hemorrhage and up to 35% fetal mortality in trauma.⁴⁶ Engorgement of the pelvic venous complex during the relative hypervolemia of pregnancy can result in massive, life-threatening hemorrhage in the event of pelvic trauma, including fetal death due to maternal shock.⁷ Direct injury to the uterus can result in placental abruption or injury to the fetus. The most common fetal injury is traumatic brain injury, especially late in pregnancy as the fetal head descends into the pelvic inlet. Angiography and angioembolization are useful adjuncts in the management of life-threatening pelvic hemorrhage.

Chart 31-3 Physiologic Changes in Pregnancy

Cardiovascular	Increased heart rate Decreased systemic vascular resistance Decreased blood pressure (first and second trimesters) Increased plasma volume
Pulmonary	Elevated diaphragm Increased tidal volume Increased minute ventilation Decreased functional residual capacity Decreased PCO ₂
Gastrointestinal	Decreased lower esophageal sphincter competency Decreased gastric motility Increased transaminase levels Impaired gallbladder contractions
Genitourinary	Increased glomerular filtration rate Increased renal plasma flow Decreased blood urea nitrogen levels Decreased creatinine levels Hydronephrosis/hydronephrosis
Hematologic	Relative anemia with increased overall RBC volume Leukocytosis Increased factors VII, VIII, IX, X, XII (hypercoagulability) Decreased fibrinolytic activity (hypercoagulability) Increased fibrinogen

Chart 31-4 Estimated Fetal Radiation Doses from Common Imaging Studies

Diagnostic Test	Fetal Dose (Rad)
Chest x-ray	<0.01
Abdominal x-ray	0.1–0.3
Pelvis x-ray	0.04–0.24
Extremity x-ray	<0.01
CT head	<0.05
CT chest	0.1–0.45
CT abdomen	0.24–2.6
CT pelvis	0.73–4.6

Abruptio Placentae

Disruption of the placenta from the uterine wall is the most common cause of late maternal bleeding and the leading cause of fetal demise after trauma.⁴⁷ Fetal mortality ranges from 30% to 70%. Shearing of the inelastic placenta off the relatively elastic uterine wall from direct trauma or deceleration leads to separation of the placenta–uterine interface and results in maternal bleeding and disruption of blood flow to the fetus. Disruption of greater than 50% of the placental surface is uniformly fatal to the fetus. However, fetal distress may not manifest until greater than 30% of disruption occurs. Risk factors for abruptio placentae include hypertension, diabetes mellitus, advanced age, multiparity, tobacco use, and cocaine use. Symptoms include abdominal pain, intense uterine contractions, vaginal bleeding, and back pain. Vaginal bleeding with abdominal pain after trauma mandates prompt ultrasonographic evaluation. Massive bleeding can occur with hemodynamic collapse, but even occult bleeding can lead to plasminogen activator–mediated fibrinolysis and DIC.⁴⁸ Delayed presentation of abruptio placentae can occur and patients with blunt injury to the abdomen should be closely monitored.⁴⁹

Uterine Rupture

Traumatic rupture due to blunt trauma is uncommon, with an incidence of approximately 0.6%, but is associated with up to 10% mortality of the mother and almost 100% mortality of the fetus.^{11,50} Most result from direct high-energy trauma to the abdomen and are associated with concurrent injuries. Risk factors include prior caesarean section or prior uterine surgery.⁵¹ Diagnosis can be challenging, as abdominal pain, often without vaginal bleeding, can be the only sign of underlying uterine rupture. Excellent outcomes in subsequent pregnancies can be achieved in those with prior uterine rupture who undergo uterine repair.⁵² An attempt at repair and subsequent vaginal delivery should be encouraged.

Amniotic Fluid Embolism

Embolism of the amniotic fluid into the maternal venous circulation is a rare, but often fatal complication of abdominal trauma or placental abruption. Mortality rates of up to 80% have been reported. Amniotic fluid embolization is characterized by sudden onset of hypoxemia, hypotension, and coagulopathy. Diagnosis is mostly clinical, though chest radiography may show evidence of pulmonary edema or bilateral scattered infiltrates characteristic of acute respiratory distress syndrome (ARDS). DIC occurs in 30% of these patients. Treatment is supportive with optimization of hemodynamics, oxygenation, and treatment of resulting coagulopathy.⁵³

Preeclampsia/Eclampsia

Preeclampsia is infrequent, occurring in up to 5% of pregnancies. Risk factors include nulliparity, diabetes mellitus, chronic hypertension, renal disease, advanced maternal age (>35 years), obesity, prior or family history of preeclampsia.⁵⁴ Signs of this syndrome include hypertension, edema, proteinuria, and hyperactive reflexes, though patients may present only with hypertension without other signs. Eclampsia, the onset of seizures with preeclampsia, occurs rarely in about 0.05% to 0.2% of pregnancies, but mandates immediate treatment with magnesium sulfate, and consideration of emergent caesarian section. An alteration in mental status in the pregnant trauma patient mandates consideration of eclampsia as an underlying cause.

Disseminated Intravascular Coagulation

Major trauma, especially those involving massive hemorrhage, abruption, preeclampsia/eclampsia, HELLP (hemolysis, elevated liver enzymes, low platelet count), amniotic fluid embolism, or SIRS (systemic inflammatory response syndrome), can lead to disruption of the hemostatic cascade. In healthy patients, tissue factor binds to factor VIIa, generating Xa. Xa binds to cofactor Va, converting prothrombin. Regulation of this cascade is complex, involving tissue factor pathway inhibitor, antithrombin, and activated protein C. Dysfunction of this regulatory mechanism leads to unchecked thrombin production, with diffuse intravascular fibrin deposition (causing end-organ damage and failure) and fibrinolysis, resulting in depletion of coagulation factors and platelets (leading to a profound bleeding diathesis). Placental abruption can release thromboplastin into the maternal circulation, resulting in severe DIC. Treating involves expedient correction of clotting deficits and emptying of the uterus.

EMERGENT CAESARIAN SECTION

Vaginal delivery is preferred whenever possible, even if labor begins during evaluation and treatment for traumatic injuries, including exploratory laparotomy and surgical intervention.⁵⁵ Indications for emergent caesarian section include maternal shock, massive exsanguination, facilitation of maternal treatment, high risk of fetal demise, and unstable thoracolumbar spinal injuries. Perimortem caesarian section can be considered if the estimated gestational age is over 26 weeks. However, the decision to perform a caesarian section must be made in an expedient manner. If performed within 5 minutes of maternal demise, survival of over 75% can be achieved in viable fetuses with fetal heart tones and >26 weeks of gestation.^{56,57} Case reports also show that 60% of mothers had either improved hemodynamics or return of spontaneous circulation after performance of perimortem caesarian section. The 2010 American Heart Association guidelines recommend perimortem caesarian section for the viable fetus, in the event of maternal cardiac arrest without return of spontaneous circulation by 4 minutes.⁵⁸ These recommendations are widely supported by national and international associations including the American College of Obstetricians and Gynecologists and the Royal College of Obstetricians and Gynaecologists.^{59,60} Early involvement of the obstetrics team facilitates the decision to perform an emergent caesarian section and ensures the timeliest delivery of the child should one be necessary.

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

9 Pregnant patients are at increased risk for DVT and PE. These patients may have venous stasis from decreased mobility, relative vena cava compression, as well as hypercoagulability due to increased production of coagulation factors. Endothelial injury is common in trauma and adds to the increased risk

in these patients (Virchow's Triad). Unfractionated subcutaneous heparin, in addition to sequential compression device use and early ambulation, is recommended in pregnancy and should be initiated once stable. Low-molecular-weight heparin appears to be safe in the treatment of DVT/PE with at least one small, randomized controlled trial showing safety and effectiveness with less bleeding complications. Coumadin is not recommended for use in treatment of DVT/PE due to difficult regulation of anticoagulation. When given in the first trimester, up to a 29% incidence of warfarin embryopathies can be seen, including mental retardation, optic atrophy, ventral midline dysplasia, and central nervous system (CNS) abnormalities. Late pregnancy administration is associated with significant risk of fetal bleeding and mortality.⁶¹ Low-molecular-weight heparin does not cross the placenta and is not associated with increased teratogenicity or fetal bleeding, and is recommended by the American College of Chest Physicians for thromboembolism prophylaxis and treatment in pregnant patients.⁶² Placement of a vena cava filter should be considered when the extent of thrombosis is extensive or patients at high risk for PE.

SOCIAL AND ETHICAL CONSIDERATIONS

10 IPV affects up to 324,000 women each year, and 4% to 9.5% of all pregnancies.^{6,63–65} IPV affects women across all age groups, religions, ethnic backgrounds, socioeconomic level, education, and sexual orientation. Care providers need to have low thresholds for screening pregnant patients for IPV, especially when patients present with multiple episodes of trauma, suspicious patterns of injury, or injury that does not correspond to the given history. Although screening during trauma evaluation can be challenging, even brief screening tools have found to be effective. Early detection and intervention, with the assistance of social work and local resources, best ensures the safety of both mother and fetus.^{66,67}

Substance abuse is increasingly seen in pregnant trauma patients. In two major urban centers, 50% to 80% of admitted female trauma patients tested positive for cocaine and/or heroin.⁶⁸ Data from the American College of Surgeons National Trauma Data Bank showed 12.9% and 19.6% of traumas in pregnant women were associated with alcohol and drug use, respectively.⁶⁹ Alcohol abuse is associated with decreased use of seatbelt restraint systems (22% vs. 46% in sober patients).⁶⁸ While seatbelt use by pregnant women is higher than in the general populace, improved education may improve outcomes given half of all fetal losses could have been prevented with proper seatbelt use.¹⁵

TEAM APPROACH TO TRAUMA IN THE PREGNANT PATIENT

A coordinated approach involving prehospital providers, the Emergency Medicine team, Nursing, Obstetrics, Obstetric Nursing, Critical Care and Surgery is key to the proper management of these patients. Involvement of the obstetric team (even prior to arrival of the patient) can be invaluable and consideration should be given for early notification.

SUMMARY

The optimal treatment of the pregnant patient requires special attention to the evolving anatomical and physiologic changes that occur during pregnancy. Evaluation and management should be tailored to the stage of pregnancy and requires a multidisciplinary, team approach. While fetal survival is best achieved by appropriate resuscitation and care of the mother, recognition of the unique patterns and complications of traumatic injury ensure the best possible outcome for the mother and fetus.

Chapter 32

Postinjury Management

Bellal Joseph and Peter Rhee

Key Points

- 1 Damage control resuscitation is critical to avoid the lethal triad of trauma: dilutional coagulopathy, hypothermia, and acidosis.
 - 2 Permissive hypotension, liberal use of blood products instead of isotonic fluids, and early correction of coagulopathy are the principles of damage control resuscitation.
 - 3 Massive transfusion protocols and early use of red cells, fresh frozen plasma, and platelets in a 1:1:1 ratio minimizes the risk of dilutional coagulopathy.
 - 4 Attempts to achieve supernormal resuscitation endpoints should be avoided to prevent complications such as abdominal compartment syndrome.
 - 5 Traumatic brain injury (TBI) remains the leading cause of death from trauma. Neurologic examination is a valuable tool and can replace repeat head CT scans in mild TBI. Initial laboratory data have prognostic value in TBI outcomes.
 - 6 Preinjury coagulopathy with home medications is common in patients with TBI and knowledge of home medications is important.
 - 7 Early use of enteral nutrition is desirable.
 - 8 Organ donation is a legitimate outcome in trauma patients. Early involvement of organ procurement networks and social services as well as aggressive resuscitation protocols improves procurement rates.
-

INTRODUCTION

Trauma is now the leading cause of death for ages 46 and below in the United States.¹ Hemorrhagic shock is the most common cause of mortality during the first 6 hours following trauma and 16% to 80% of those deaths may be preventable.² Postinjury management predominantly focuses on two goals, early control of bleeding and resuscitation.

ACUTE TRAUMATIC COAGULOPATHY

Coagulopathy is known to worsen posttraumatic hemorrhage and is associated with increased mortality and worse outcomes. Interestingly, up to 25% of trauma patients are already coagulopathic upon arrival to the hospital.^{3,4} Current data suggest that coagulopathy develops in the early posttraumatic period even before resuscitation begins and is now referred to as acute traumatic coagulopathy.^{4–6} Diffuse endothelial damage, activation of the protein C pathway, and massive catecholamine release are some of the proposed mechanisms for acute traumatic coagulopathy.⁷ Acute traumatic coagulopathy may be exacerbated by hypothermia, acidosis, and dilution of clotting factors.

1 Hypothermia in trauma patients results from a multitude of factors that include radiant heat losses to the environment, failure of shivering response during anesthesia, intraoperative heat loss from exposed peritoneal surfaces, and tissue hypoxia during hemorrhagic shock with decreased metabolism. Another major cause of hypothermia is the use of relatively cool room temperature resuscitation fluids or cold refrigerated blood products that were not warmed before infusion.^{8–10} These cumulative factors produce qualitative and quantitative defects in platelet function and decrease coagulation factor activity.^{11–13} In addition to reducing coagulation factor activity, dilutional coagulopathy from large-volume crystalloid resuscitation and acidosis from prolonged tissue hypoxia perpetuates the bloody vicious cycle.^{14,15} The combined presence of three factors, hypothermia, acidosis, and coagulopathy, is

known as the “lethal triad.” Modern trauma resuscitation is defined as damage-controlled resuscitation and aimed at reducing the iatrogenic development of this “lethal triad.”

DETECTION OF TRAUMATIC COAGULOPATHY

The early identification of acute traumatic coagulopathy remains a challenge. Conventional coagulation assays like PT, aPTT, and INR are insensitive and unreliable in trauma patients, as they do not provide an accurate assessment of the *in vivo* state of coagulation. Moreover, these assays are performed at physiologic pH and temperature; because of this they are unable to account for the effects of hypothermia and acidosis on coagulation.⁷ Acute traumatic coagulopathy involves changes in both coagulation and fibrinolytic pathways, and detection requires a more dynamic view of all components of the coagulation cascade, which is provided by viscoelastic tests, that is, thromboelastography and rotational thromboelastometry. These assays rely on changes in clot strength to detect coagulation defects and provide an *in vivo* picture of the coagulation and fibrinolytic processes. These tests also assess the interaction between coagulation factors and platelets and can detect functional changes in platelet function even with normal platelet counts. They can be performed with much more rapidity and have been shown to detect coagulation abnormalities with higher sensitivity as compared to conventional coagulation assays.^{16–18} Viscoelastic tests have also shown to be more accurate in predicting blood product requirements and massive transfusion and can therefore guide blood transfusion in trauma patients.^{19,20} Despite these advantages, viscoelastic tests come with inherent disadvantages such as cost and the need for greater expertise in performance and interpretation.

DAMAGE CONTROL RESUSCITATION

The primary objective of resuscitation following hemorrhage is to restore effective circulating volume to allow adequate tissue perfusion and oxygenation. Historically, the standard of practice has been to aggressively resuscitate patients with high volumes of crystalloids to restore volume and blood pressure. In recent years, there has been a paradigm shift away from the large-volume resuscitation. Current strategies combine the principles of permissive hypotension, liberal use of blood products instead of isotonic fluids, the use of hypertonic saline to pull water back into the vascular system, and early correction of coagulopathy with blood products as well as drugs ([Table 32-1](#)).

2 Permissive hypotension aims at restoring systolic blood pressure to 90 mm Hg so that adequate tissue perfusion can be maintained while not exacerbating blood loss, before definitive hemorrhage control is achieved. Large-volume resuscitation with crystalloids before definitive hemostasis can raise blood pressure which can “pop off” the clot and worsen hemorrhage.²¹ A target mean arterial pressure (MAP) of around 60 mm Hg is thought to maintain adequate tissue perfusion without the potential for increased blood loss.^{22,23,24,25}

A brief period of hypotension with a MAP around 60 mm Hg can be safely maintained for short periods of time without risk of irreversible damage or an increase in mortality.²⁶ Permissive hypotension has been shown to reduce the risk of death and development of coagulopathy.^{3,27} However, in patients with hemorrhagic shock and concurrent traumatic brain injury (TBI), the safety of permissive hypotension has not been demonstrated and thus it is not yet recommended.²⁸

Up to 5% of civilian trauma patients require massive transfusion, defined as the need for more than 10 units of red blood cells in 24 hours. These patients are at greatest risk for developing dilutional coagulopathy from large volumes of resuscitation even if packed red cell transfusion is used early in the resuscitation phase. Damage control resuscitation (DCR) utilizes massive transfusion protocols and early use of red cells, fresh frozen plasma, and platelets in a 1:1:1 ratio in an attempt to reconstitute whole blood. The use of blood products early in the course of resuscitation is not only an attempt to combat the coagulopathy in trauma patients requiring massive transfusion but to also minimize the use of crystalloids and colloids.^{29–31}

The use of predefined massive transfusion protocols has shown improved survivals and decrease in adverse outcomes.^{32,33} This approach requires the ability to predict the need for massive transfusion in trauma patients at the time of arrival which is often difficult even for experienced surgeons. Multiple scoring systems have been developed to help define the cohort requiring massive transfusion.^{34,35}

3 The appropriate ratios of packed red cells, fresh frozen plasma, and platelets in exsanguinating

trauma patients have been debated. The concept of a 1:1:1 ratio stems from military data which show improved survival with the use of fresh whole blood. Since civilian trauma centers do not have fresh whole blood available, component therapy is an attempt to reconstitute whole blood by giving red cells, fresh frozen plasma, and platelets in a nearly physiologic ratio. Most studies have shown improved mortality with the use of high plasma and pRBC ratios with even greater survival in those with early (6 to 12 hours) use of high ratios.^{5,8,36–41} The use of a 1:1 ratio for pRBC and platelets has also shown improved survival.³⁸ Despite the survival advantage with the use of a 1:1:1 ratio for transfusion, the potentially lethal complications of blood transfusion need to be kept in mind. The PROPPR trial which was a multicenter prospective randomized study in hemorrhagic trauma patients demonstrated an early survival benefit when the patients were resuscitated with a 1:1:1 ratio compared to a 2:1:1 ratio but the 28-day mortality was not statistically significantly different.

Table 32-1 Components of Damage Control Resuscitation

■ Permissive hypotension
■ Early definitive hemorrhage control
■ Reduced crystalloid use
■ Use of hypertonic saline
■ Early correction of coagulopathy with drugs (Factor VIIa, PCC, TXA)
■ Increased use of blood products in 1:1:1 ratios

PCC, Prothrombin complex concentrate; TXA, Tranexamic acid.

Hypertonic saline has many potential advantages in that it can resuscitate with low volume by pulling water into the vascular space and thus avoids excess water during resuscitation. This concept has advantages especially in the military field environment. Hypertonic saline is also thought to be an immune modulator that potentially decreases inflammation associated with resuscitation injury.⁴² However, a multicenter prospective trial in trauma patients with hemorrhagic shock was halted before completion as the outcome was similar between the groups. Overall there was no survival disadvantage in the hypertonic saline arm of the study except in a small subset of patients who did not require blood transfusion. This subset of patients had higher mortality if given hypertonic saline in the field. There was also a subset that required ICU treatment that showed higher survival and decreased multiple organ failure when hypertonic saline was given.⁴³ Since 7.5% hypertonic saline is not commercially available, an alternative is to use 5% hypertonic saline. Those who use 5% hypertonic saline administer it as a one-time bolus in the initial phase of resuscitation. This approach may be beneficial in patients with TBI. The safety of using 5% hypertonic saline has been shown in two studies.^{44,45} A caveat of using hypertonic saline is that it causes hyperchloremic acidosis, but clinical significance has not yet been demonstrated. Because of the capability of increasing intravascular volume, the ideal time and place for hypertonic saline use may be in the field, especially in the military setting.⁴⁶

Hyperfibrinolysis associated with traumatic coagulopathy may decrease levels of fibrinogen. High plasma:pRBC ratios adequately replenish the fibrinogen pool required for adequate hemostasis and thus the use of cryoprecipitate rich in fibrinogen as an adjunct to DCR is rational.⁸ The use of cryoprecipitate has additional advantages as it provides particles that act as a low-volume colloid resuscitation and draw water into the vascular system, and is an adjunct in resuscitation. Tranexamic acid is an antifibrinolytic agent found to be safe and effective in reducing the risk of bleeding if used within 3 hours of injury.⁴⁷ The military Tactical Combat Casualty Care Committee has recommended its use in the military setting. Several other novel strategies have also been used as an adjunct in DCR including the use of activated recombinant factor VII (rFVIIa). rFVIIa activates factor Xa at the site of tissue injury by complexing with tissue factor on the surface of platelets. Use of rFVIIa has shown to effectively reduce blood loss and mortality in massive trauma patients; its use is limited by high costs.^{48,49} Prothrombin complex concentrate (PCC) is another cost-effective option that reverses coagulopathy in traumatic injury.⁵⁰

The discussion of DCR should also include damage control laparotomy. After injury, when a trauma patient requires laparotomy, some patients may require abbreviated laparotomy in order to better resuscitate the patient so that the prolonged initial surgery does not harm the patient. Although damage control laparotomy has been widely accepted as the standard of care for trauma patients, it was adopted without rigorous proof of concept. One hallmark study suggested that damage control laparotomy is of benefit in trauma patients with numerous major visceral injuries that also have vascular injury; this study also showed that damage control laparotomy in patients without major injuries was associated with worse outcome.⁵¹ Definitive laparotomy may have survival benefit with decrease in morbidities

known to accompany damage control laparotomy such as open abdomens and enterocutaneous fistulas. Because of the decreased number of surgeries and morbidities, the cost benefits were significant.^{52,53}

ENDPOINTS OF RESUSCITATION

The ultimate goal of resuscitation is to ensure adequate oxygen delivery to tissues. Prolonged tissue hypoxia is associated with multiorgan dysfunction syndrome, risk of infection, and increased mortality.

Advanced Trauma Life Support guidelines define the correction of vital signs like blood pressure and heart rate as markers of adequate resuscitation. However, up to 82% of severely injured patients with normalized vital signs have ongoing occult ischemia that is associated with adverse outcomes.⁵⁴ While normalization of vital signs may describe the current perfusion status, they do not assess oxygen debt, defined as ongoing oxygen deficits that have accumulated during the period of shock. Oxygen debt is known to be associated with increased mortality.^{55,56} Arterial lactate and base deficit may serve as indicators for severity of shock and may help to stratify patients. Trends in serum lactate levels indicate adequacy of resuscitation.

Invasive monitoring with central venous pressure (CVP) and pulmonary artery catheter (PAC) have been extensively used to guide resuscitation. CVP and pulmonary capillary wedge pressure monitoring provide information regarding the intravascular volume, but concurrent factors like mechanical ventilation and changes in ventricular compliance from myocardial dysfunction limit their efficacy in accurately guiding resuscitation.⁵⁷ Moreover, PAC use in critically ill trauma patients has not been shown to improve outcomes.⁵⁸

ScVO₂ and SVO₂ measure central venous oxygen saturation from the upper body and mixed venous oxygen saturation from both the upper and lower body, respectively. Inadequate oxygen supply from ongoing shock or increased oxygen demand leads to an increased tissue extraction of oxygen, which is reflected as a decrease in the values of ScVO₂ and SVO₂. SVO₂ of less than 65% even in the presence of normal vital signs indicates blood loss and need for transfusion to optimize oxygen supply and demand.⁵⁹ Therefore, ScVO₂ and SVO₂ provide a real-time picture of tissue perfusion and are able to detect very subtle changes in oxygen delivery. The ideal marker for resuscitation may be to determine blood volume, but there is currently no simple way to determine ideal circulating blood volume.

ABDOMINAL COMPARTMENT SYNDROME

4 Abdominal compartment syndrome is an undesired consequence of elevated intra-abdominal pressure and a cause of morbidity and mortality.⁶⁰ The incidence of abdominal compartment syndrome is decreasing with recent evolution in resuscitation strategy, suggesting a possible iatrogenic etiology.⁶¹ Intra-abdominal hypertension is defined as a pressure of greater than or equal to 12 mm Hg. Intra-abdominal hypertension is graded based on increasing intra-abdominal pressure (Table 32-2). Abdominal compartment syndrome is defined as a sustained intra-abdominal pressure greater than 20 mm Hg (with or without an abdominal perfusion pressure of less than 60 mm Hg) with new organ dysfunction or failure.⁶² Experimental data indicate that hepatic arterial, portal venous, and hepatic microcirculatory blood flow are markedly reduced when intra-abdominal pressure is increased.^{62,63} Typically, abdominal compartment syndrome is observed after severe abdominal trauma with intra-abdominal hemorrhage, severe liver and kidney injuries, and in both operatively and nonoperatively managed settings (primary abdominal compartment syndrome).^{64–66} Excessive large-volume resuscitation, even in the absence of any direct abdominal trauma, can also lead to abdominal compartment syndrome (secondary abdominal compartment syndrome).^{67–69} Recurrent or tertiary abdominal compartment syndrome refers to a condition following a previously treated primary or secondary abdominal compartment syndrome.⁶² Risk factors for development of abdominal compartment syndrome include diminished abdominal wall compliance, increased intraluminal and intra-abdominal content, crystalloid resuscitation/leak, and other risk factors such as age, shock, high BMI, coagulopathy, and mechanical ventilation.^{70–80} Abdominal compartment syndrome can even occasionally occur in patients with an open abdomen. The diagnosis often begins with findings of a tense and distended abdomen in the presence of high end-inspiratory airway pressures and other signs of organ dysfunction (i.e., oliguria, rising serum creatinine). Additional clinical signs consistent with abdominal compartment syndrome are a reduced cardiac output, elevated systemic vascular resistance, and elevated pulmonary capillary wedge pressure with simultaneous low or normal calculated estimates

of end-diastolic volume. The standard for monitoring intra-abdominal pressure is bladder pressure measurement via intravesical technique. Bladder pressure is measured in end-expiration with the patient supine, by distending the bladder with 25 mL of sterile saline.^{81,82}

Table 32-2 Grades of Intra-abdominal Hypertension

Grade	Intra-Abdominal Pressure
I	12–15 mm Hg
II	16–20 mm Hg
III	21–25 mm Hg
IV	>25 mm Hg

Surgical decompression of the abdomen is an option for established abdominal compartment syndrome with associated organ dysfunction and persistent shock with no absolute thresholds for urine output and airway pressure.⁸³ Protocols on fluid resuscitation are recommended to avoid a sustained increase in intra-abdominal pressure.⁸⁴ In addition to decompressive laparotomy for abdominal compartment syndrome, numerous medical and minimally invasive therapies have been proposed such as sedation and analgesia for anxiety relief and brief trials of neuromuscular blockade as temporizing measures. Body positioning and colonic/nasogastric decompression are also suggested noninvasive treatment options.^{85–87} Patients with abdominal compartment syndrome may have ascites and drainage of fluid with various catheters can be tried before performing decompressive laparotomy as a less invasive alternative. A common factor among all cases of abdominal compartment syndrome seems to be the use of aggressive crystalloid resuscitation causing resuscitation injury. Use of excessive crystalloid resuscitation is discouraged in DCR and studies show decreased rates of abdominal compartment syndrome in association with decreased rates of crystalloid resuscitation.⁶¹ Attempts to achieve “supranormal” endpoints (cardiac index of >4 L/min/m² or oxygen delivery index of >600 mL/min/m²), while theoretically desirable, have not been shown to be effective as this often requires excessive resuscitation volumes that contribute to abdominal compartment syndrome.⁸⁸ As resuscitation has changed with DCR, the incidence of abdominal compartment syndrome has been decreasing. In the trauma setting, abdominal compartment syndrome has been disappearing rapidly but in the general surgery setting, it is more common. Sepsis as a source of inflammation can create abdominal compartment syndrome even when resuscitation injury is minimized. Source control of the bacterial contamination is the best treatment for abdominal compartment syndrome. End organ failure with microcirculatory disruption and endothelial leak is another source of the syndrome.

TRAUMATIC BRAIN INJURY

5 TBI remains one of the leading causes of injury-related deaths. Initial management of TBI includes hyperosmolar resuscitation, intracerebral pressure (ICP) monitoring, and prevention of hypoxia and hypotension.

Secondary Brain Injury

Injury prevention and better safety are the mainstays for primary brain injury. After the initial insult, the main goal is to prevent or minimize secondary brain injury. Secondary brain injury can be influenced by a cascade of inflammatory responses, occurring as a consequence of the primary injury. Secondary brain injury is also exacerbated by potentially preventable factors such as hypotension, hyperthermia, seizure activity, hyperglycemia, and hypoxemia.

Hypotension at any point (even brief time periods) is associated with a doubling of mortality in patients with severe TBI.^{89,90} Although hyperventilation temporarily reduces intracranial pressure and may help to prevent herniation, evidence suggests that excessive hyperventilation may be harmful for patients with TBI. Therefore, brief hyperventilation is only recommended in order to reduce ICP temporarily until surgical decompression can be performed.

Imaging in Traumatic Brain Injury

Computed tomography (CT) scanning remains an essential tool in the initial evaluation and postinjury management of TBI. Patients with mild and moderate TBI who are examinable and not on any anticoagulant medications can be monitored by clinical examination without the need for routine serial

CT scans of the head.^{91–93} With technologic improvements made to the CT scanners around the world, the incidence of TBI has been increasing. Small insignificant intracranial radiologic findings are the main reason for the increase in the diagnosis of TBI. With increased awareness of mild TBI and with the increased attention to mild TBI with posttraumatic stress disorder, CT scans of the head are being ordered more often and routinely. In trauma, the single most common reason for obtaining a CT scan of the head has been loss of consciousness. Thus increased screening for TBI and improved technology identifying small clinically insignificant intracranial injuries has resulted in the increase of incidence of TBI. TBI is a clinical diagnosis and not just a radiographic diagnosis. There are patients with TBI with normal CT scans of the head who have cognitive deficits as well as posttraumatic stress disorder and there are many with radiographic TBI that do not have clinical deficits. Therefore, significant deterioration in neurologic examination should be considered in the decision for whether repeat head CT scan or consultation of a neurosurgeon is needed. CT scans and neurosurgical consultations are valuable resources with costs to the health care system as well as to the patient. The use of routine repeat head CT and neurosurgical consultations should be restricted to patients on prehospital antiplatelet and anticoagulants, and those with depressed skull fractures. A Brain Injury Guideline has been developed which helps guide when the resources should be used (Table 32-3).^{94–96}

Progression of lesions on repeat head CT can promptly identify patients who require more invasive neurosurgical interventions and medical therapies. Routine repeat head CT is still recommended for those patients with GCS less than 8 and for those who do not have a reliable clinical examination such as patients that are under general anesthesia or patients that are in the ICU under sedation.

Coagulopathy in TBI

A decreased platelet count (less than 100,000/ μ L) and/or impaired platelet function after TBI is associated with progression of intracranial hemorrhage, need for neurosurgical intervention, and mortality.^{97–99} Admission INR greater than 1.5 also predicts progression of intracranial hemorrhage. The treatment of coagulopathy after TBI is multipronged due to the complexity of the problem. Therapeutic strategies should focus on the treatment of the primary cause and controlling the progression of intracranial bleeding. fresh frozen plasma, platelets, recombinant factor VII, and PCC can be used in various combinations to improve outcomes.^{100,101}

Antiplatelet and Anticoagulation Therapy in TBI

6 Antiplatelet medications, anticoagulants, and nonsteroidal anti-inflammatory drugs are among the most frequently encountered medications in TBI patients, especially the elderly. Existing evidence shows an increased risk of progression of intracranial bleeding in patients on high-dose aspirin and clopidogrel, whereas low-dose aspirin and ibuprofen do not cause progression on CT or neurologic examination.^{102–104} A platelet count of less than 135,000/ μ L in patients on antiplatelet therapy is predictive of both radiographic and clinical worsening.¹⁰⁵ Reversal of the effect of anticoagulants and antiplatelets is suggested to improve the outcomes.

Table 32-3 Brain Injury Guideline

Variables	BIG 1*	BIG 2
Neurologic examination	Normal	Normal/abnormal
Intoxication	Yes/no	Yes/no
CAMP	No	Yes/no
Skull Fracture	No/simple, nondisplaced	Other
SDH	≤ 4 mm	> 4 mm
EDH	≤ 4 mm	> 4 mm
IPH/Contusion	One location and ≤ 4 mm	Other
SAH	Trace/pinpoint	Other
Therapeutic Plan		
Neurosurgical Consult	No	Yes
RHCT	No	Yes
ICU admission	No	Yes

*Patients should meet all Criteria for BIG 1.
Intoxication, alcohol/drugs; CAMP, coumadin, aspirin, motrin, plavix; SDH, subdural hematoma; EDH, epidural hematoma; IPH, intraparenchymal hemorrhage; SAH, subarachnoid hemorrhage; IVH, intraventricular hemorrhage; RHCT, repeat head CT; NSC, neurosurgical consult.

Use of newer oral anticoagulants like direct thrombin inhibitors and factor Xa inhibitors is increasing.

Despite their safety advantage over coumadin, concerns for progression of intracranial bleed and adverse outcomes exist in TBI patients.^{106,107} No specific reversal agents are yet available for newer oral anticoagulants. Oral charcoal administration, hemodialysis, PCC, and rFVIIa have shown some efficacy in the reversal of these agents.^{108–113}

Seizure Prophylaxis after TBI

Posttraumatic seizures increase the cerebral metabolic rate, ICP, and may cause secondary brain injury. Seizures after TBI are associated with worse outcome. It is not known if poor outcomes are due to underlying injury which is associated with posttraumatic seizures or if posttraumatic seizures exacerbate injury. Studies have shown that prophylactic therapy with phenytoin during the first 7 days after injury is effective in reducing the number of early posttraumatic seizures.¹¹⁴ Long-term use of prophylactic anticonvulsants has not been shown to be of benefit. Anticonvulsant prophylaxis is not indicated for late onset posttraumatic seizures (after 7 days). Because phenytoin is cumbersome to use, as it requires frequent drug-level monitoring and can lead to neurodepressive side effects, the use of levetiracetam has become common. However, recent studies have shown that the seizure rate after TBI is very low and the use of levetiracetam has not equated to reduced seizures.¹¹⁵

Penetrating Brain Injury

Gunshot wounds to the brain are the most lethal of all firearm injuries. Aggressive postinjury resuscitation is associated with significant improvement in both survival and organ donor eligibility.^{116,117} Early aggressive management includes blood products, hyperosmolar therapy, vasopressors, and/or PCC. Early aggressive T4 (levothyroxine) therapy and correction of coagulopathy increases the organ donation rate in nonsurvivable patients.^{116,118}

NUTRITIONAL AND METABOLIC SUPPORT

Nutritional support after injury imparts significant acute and long-term effects on outcomes. Understanding of the nutritional and metabolic derangements following injury has increased exponentially over the past few decades. This has resulted in a more focused and goal-oriented approach toward nutritional support. Once patients are stabilized and recovered from shock, attention should be directed to metabolic and nutritional support.

The route of administration and timing of initiation of nutritional support have been issues of controversy. Current evidence supports the use of enteral nutrition in all trauma patients as soon as possible.^{119–124} There are certain situations where enteral nutrition is not a feasible option; in such patients total parenteral nutrition is an alternative. Even in cases where enteral nutrition cannot be administered due to frequent or impending operative intervention or intolerance of enteral feeding, total parenteral nutrition should be used as a bridging measure. The literature on nutritional support in critically injured trauma patients consistently reports higher septic morbidity in patients on total parenteral nutrition.^{122–125} Current guidelines on the nutritional support provide a level 1 recommendation on the advantages of enteral nutrition over nutritional support via the parenteral route.¹²⁶

7 Recent recommendations aim for early enteral nutrition. The definition of early varies in the literature, ranging from a few hours after injury up to 72 hours.^{124,125} Although the benefits are yet to be established, safety of early (within 24 hours of injury) enteral feeding is well documented.¹²⁶ In patients with severe burns it is recommended to initiate enteral feeding within 18 hours of injury.¹²⁷ Early feeding in this group of patients reduces the risk of gastroparesis. In the case of severe TBI enteral feeding is safe and should be administered early.^{128–130}

Nasogastric and nasojejunal routes are the preferred modes of initial nutritional access. If long-term nutritional support is required, the planning of feeding access should be based on individual patient circumstances. In patients undergoing laparotomy, insertion of a surgical feeding tube either in the stomach or small intestine is a feasible option. For patients in need of long-term nutritional support and not requiring surgical intervention the preferred route is via endoscopically guided percutaneous feeding tube. The percutaneous endoscopic route is increasingly popular, but the literature is not well established on its safety and complications.^{131,132} While choosing one route over the other, special consideration should be given to individual patient factors as there is no single feeding access that stands out among the others for safety and efficacy.^{133–136}

The goal of nutritional support during postinjury phase is twofold, first to provide enough calories to meet basal energy expenditure and second to complement the special micronutrient requirements of ongoing inflammation. Basal energy expenditure during postinjury phase ranges from 30 to 35 kcal/kg/day. Basal energy expenditure is higher in TBI patients and lower in spinal cord injury patients. The estimation of basal energy expenditure in critically ill patients remains challenging and current calculators frequently overestimate caloric requirements. A high-caloric dietary supplementation is associated with hyperglycemia, hypercapnia, and higher in-hospital complications.¹³⁷ While underfeeding is also a concern in critically ill patients, a more balanced approach is permissive underfeeding. Permissive underfeeding focuses more on maintaining nitrogen balance than meeting caloric requirements alone. Diets containing higher protein content and lower caloric value than target serve such a purpose. Permissive underfeeding results in better glycemic control, rapid recovery, and overall better in-hospital patient outcomes.^{138–140}

In the setting of trauma and critical illness, the ongoing catabolic response demands special micronutrients and dietary considerations along with standard protein and caloric replacement. Nonessential amino acids such as arginine and glutamine become conditionally essential. Addition of these amino acids along with omega-3 fatty acids to standard dietary formulas has been shown to improve outcomes and immune function. Enhanced diets containing higher protein content, and including a combination of arginine, glutamine, omega-3 fatty acids, minerals (zinc, copper, etc.), nucleic acids, and vitamins have shown to improve overall immune function.^{141–144}

The assessment of nutritional requirement in critically ill patients is primarily done by the indirect calorimetry method. The standard measure of nutritional requirement uses a metabolic cart, but this is expensive and cumbersome.¹⁴⁵ An alternative approach uses predictive equations but these are imprecise and often over- or underestimate the nutritional requirement.¹⁴⁶ In recent years, several handheld indirect calorimeters have been marketed. They provide ease of use as they are portable and relatively accurate.¹⁴⁷ To assess the adequacy of nutritional supplementation, anthropometric measurements and biochemical data can be utilized. While there is no single measure which accurately predicts adequacy of nutritional support, prealbumin levels provide a reliable estimate compared to albumin, transferrin, and retinol-binding protein.¹⁴⁸

ORGAN DONATION

Trauma donors are the major contributor in the organ donation pool.¹⁴⁹ There remains great potential to enhance the conversion rate in this group of trauma donors. Over the past decade significant changes occurred in resuscitation protocols in general and specifically in potential organ donors. These changes in resuscitation have resulted in better organ donation in this group of potential donors.

Wide spread acceptance of DCR has led to better end-organ preservation, which not only improves outcomes in surviving patients but can improve overall organ donation rates in patients who become brain dead. The guidelines defining organ donor management recommend continuation of this aggressive resuscitative support even after declaration of brain death.^{118,150}

A feasible goal for resuscitating any potential donors is to follow a rule of 100's that is, maintaining a systolic blood pressure of >100 mm Hg, heart rate of <100 bpm, urinary output >100 mL/hr, and paO_2 >100 mm Hg. Along with hemodynamic resuscitation, focus should also be given to pulmonary edema, coagulopathy, and hypothermia. Coagulopathy and hypothermia are not only associated with adverse outcomes in trauma patients but also render them ineligible for organ donation.¹⁵¹

The focus of resuscitative efforts after declaration of brain death shifts from cerebral preservation to organ preservation. The shift in resuscitation focus is a continuum of ongoing resuscitation.¹⁵² Donors should be managed in a critical care setting and attention should be directed toward moderation of postbrain death physiologic changes. Along with ongoing resuscitation, initiation of a T4 protocol should ensue. T4 protocol or hormone replacement therapy takes into account the disruption of hypothalamic–pituitary axis.¹⁵³ The essential components of the T4 protocol include methylprednisolone, triiodothyronine (T3)/levothyroxine (T4), arginine, vasopressin, and insulin. The goal of this resuscitative cocktail is to prevent potential cardiac arrhythmias, diabetes insipidus, hypotension, and metabolic acidosis. Early initiation of hormonal therapy has shown improved organ donation rates and should be considered in all brain-dead potential organ donors.^{154–156}

8 Organ donation is a legitimate outcome in trauma patients. As aggressive resuscitation protocols for trauma patients closely align with donor management goals, the spectrum of care in potential organ

donors can easily be extended to address organ preservation. Trauma patients presenting with previously fatal neurologic injuries provide an excellent cohort where aggressive resuscitation can not only improve survival rates but also the organ donation rates.^{118,157} The care of a potential organ donor is a multidisciplinary task. Involvement of organ procurement networks and social services can improve the communication between the treatment team, procurement agency, and the donor's relatives. Bridging this gap is of utmost importance as family decline still remains a major cause of loss of potential donors.

Chapter 33

Environmental Injuries

J. Patrick Walker and Gregory J. Jurkovich

Key Points

- 1 Of the 3,000 species of snakes worldwide, only 600 are venomous, with approximately 6 deaths per year in the United States caused by snakebite. In contrast, there are over 150,000 species of Hymenoptera in the world that cause approximately 40 deaths per year, mostly as a result of severe anaphylactic reactions.
 - 2 Snakebite morbidity depends on the type of snake and the degree of envenomation. Venoms consist of numerous polypeptides that can disrupt endothelial cells and blood flow, produce neuromuscular blockade, or generate a coagulopathy via procoagulants. Some snakes (particularly Elapids [represented by the coral snakes in North America]) also have direct neurotoxins and cardiotoxins.
 - 3 Snakebite produces immediate pain, edema, and erythema at the site. Spread of the swelling greater than 30 cm/hr indicates severe envenomation. Initial incision and suction and the use of a proximal tourniquet are contraindicated. Use of purified ovine antivenin is effective for serious Crotalidae envenomation and has replaced equine antivenin with its associated risk of serum sickness. Because of the presumed safety of the newer antivenom, overuse is more likely.
 - 4 Spider bites produce toxicity by local tissue necrosis (brown recluse and hobo spiders) and painful muscle contractions (black widow spider). Death may be caused by stinging Hymenoptera, including bees (particularly aggressive Africanized bees), fire ants, and scorpions. The death is usually secondary to anaphylaxis, but occasionally massive envenomation occurs – especially with Africanized honeybees. The estimated lethal dose is approximately 20 stings/kg in most mammals.
 - 5 Hypothermia risk is high in the severely injured patient as a result of exposure, loss of normal protective metabolism (i.e., shivering), rapid massive infusion of cold fluids/blood, and open thoracic and abdominal cavities.
 - 6 The initial response to hypothermia is an intensive sympathetic type reaction with tremulousness, profound vasoconstriction, marked increase in oxygen consumption, and accelerated heart rate and minute ventilation. As core temperature falls to 33°C and 30°C this response is lost, and deeper core hypothermia rapidly develops.
 - 7 Hypothermia increases risk of mortality at every level of traumatic injury. There is no improvement in outcome when applied to the severe TBI, and patients rapidly rewarmed require less resuscitation volume and have improved survival.
 - 8 Treating hypothermia begins by preventing further heat loss and allowing endogenous rewarming. Active rewarming has many adjuncts, including warm blankets, heating pads and lights, and immersion in warm water or internally by core rewarming. Internal core rewarming is more effective, and includes heated intravenous fluids; heated body cavity lavage; heated moist inhaled air; extracorporeal circulatory rewarming (ECMO or CPB) or closed circuit intravascular countercurrent heat-exchange devices.
 - 9 Frostbite involves ice crystal formation and unpredictable loss of tissue. Early definitive rewarming (avoiding refreezing) by submersion in 40°C to 42°C water is preferable with subsequent meticulous care, awaiting demarcation, and avoidance of early débridement to optimize outcomes and tissue salvage.
 - 10 Early thrombolytic therapy might be beneficial in select frostbite patients.
-

Although most of us will not suffer a gunshot wound or a small bowel obstruction, we will all receive insect bites and those of us who frequent the outdoors will be exposed to many other facets of the environment. This chapter is about those encounters – the heat, the cold, venomous bites and stings. It is essential that all physicians know the basics of care for injuries produced in this manner.

ENVENOMATION

Snakebite

The legends and lore of snakes are spread across history; with serpents mentioned in 42 Bible verses, implicated in the death of Cleopatra, and the medical field – the snake is essential to the rod of Aesculapius and the Caduceus. Few emergencies have been surrounded with as many types of treatment (some very innovative – electrical shock and TASER, tourniquets with ice emersion, crosscut of the bite with suction of the wound) and little scientific fact as a snakebite. We will attempt to address the management of envenomation with as much evidence as possible.

There are over 1.8 million poisonous snakebites in the world annually with almost 100,000 deaths.¹ In the United States, the CDC estimates there are 7,000 to 8,000 bites per year with 5 to 6 deaths.² Most of the deaths are secondary to Rattlesnake envenomation, with only two fatalities from Copperhead snakebite in the past 5 years.

1 More than 3,000 species of snakes exist in the world of which approximately 600 are venomous. They range in size from 10 cm to greater than 9 m.³ Nonvenomous snakes predominate on all continents with the exception of Australia. There are five families of poisonous snakes worldwide: Colubridae, Elapidae, Hydrophidae, Viperidae, and Atractaspididae. The boomslang and the bird snake represent the Colubridae – found mostly in Africa. The Elapids are found throughout the world and include snakes, such as mambas, kraits, adders, and cobras. The only Elapids in North America are the coral snakes. The Hydrophidae are the sea snakes. The Viperids have long hinged fangs. They include the pit vipers that, like the Boidae family (boas and pythons), have infrared sensors in a nasal pit that is located between the nose and the eye (Fig. 33-1). These are excellent sensitive organs that can differentiate a temperature differential of 0.003°C. All venomous snakes in North America with the exception of the coral snakes are in this family. Poisonous snakes in North America are therefore of the phylum Chordata, class Reptilia, order Squamata, suborder Serpentes, and of the Crotalidae (subfamily Crotalinae) or Elapidae family. Venomous snakes are distributed throughout the United States with at least one species in every state with the exception of Hawaii, Alaska, and Maine. Water moccasins are found primarily in the Southeastern United States. Copperheads are found from Massachusetts westerly to Illinois and to the south from Florida to Texas. Rattlesnakes are found coast to coast. The genus *Crotalus* – the true rattlesnakes – are found only in the New World.

Figure 33-1. Heat sensor – nasal pit. (Photo courtesy of Ronny Stewart, MD.)

Snakes are easily identifiable reptiles, marked anatomically by the large number (greater than 120) of precloacal vertebral bodies. They also have a reduced (almost absent) left lung, a single ventricle (no ventricular septum), and no muscles in the ciliary body of the eye. Despite the absence of a ventricular septum, oxygenated and deoxygenated blood channels fairly separately through the heart.⁴ All snakes are strictly carnivores. The size of the snake dictates the size of the prey.

The pit vipers (the genus *Crotalus*, *Sistrurus*, and *Agkistrodon*) are morphologically distinguished by elliptical pupils, a triangular head, (Fig. 33-2) and retractable fangs. The fangs are tubular; injecting venom similar to a hypodermic needle. This is in contradistinction to the Elapids in which the fangs are fixed and grooved – wicking the venom into the victim. Venomous snakes have a single row of caudal plates distal to the anal plate, whereas harmless snakes have a double row of caudal plates. There are 32 species of rattlesnakes in the New World, ranging from southern Alberta to central Argentina.⁵⁻⁷

Rattlesnakes are only found in the Americas. All true rattlesnakes have a rattle (with the exception of an endangered species in Mexico – the Santa Catalina rattlesnake, which has only a vestigial rattle). The rattle is a series of interlocking segments. A new segment is added with each shedding of the skin, which may occur 2 to 3 times per year. There are two genus of rattlesnakes; *Crotalus* – the true rattlesnakes and *Sistrurus* – the pigmy rattlers. There are 14 species of *Crotalus* (Table 33-1) in North America. The largest species of rattlesnake in North America is the eastern diamondback (*Crotalus adamanteus*), which is slightly larger than its cousin the western diamondback (*Crotalus atrox*). There are eight members of the *Agkistrodon* genus – moccasins and copperheads (Table 33-2).

Figure 33-2. Triangular shape of pit viper head. (Photo courtesy of Ronny Stewart, MD.)

By far the most critical step in management of snakebite is identification of the offending species. The majority of snakebites are nonvenomous and require no treatment. Some bites, such as those of copperheads (Fig. 33-3) and pigmy rattlers (Table 33-3), are almost always self-limiting and require little more than observation. Others such as the diamondback (Fig. 33-4) and Mojave rattlers can require intense medical management, occasional surgical management, and even rarely cause death. Identification of the species by the patient is notoriously invalid; however, a detailed description of the offending snake should be taken. The only snake where color is useful in identifying is the coral snake—red and yellow kill a fellow, red and black venom lack (Fig. 33-5). Note that this is true only in North America, as there are venomous coral snakes in Central and South America that have red bands touching black bands. Other clues, such as geography and topography (proximity to water), can also at least help with identification of the genus. All snakebites should, at least initially, be considered an event with potential morbidity and possible mortality.

Table 33-1 Crotalus Species

US Rattlesnakes – Genus <i>Crotalus</i>
Timber rattlesnake (Canebrake) – <i>Crotalus horridus</i>
Eastern diamondback – <i>Crotalus adamanteus</i>
Western diamondback – <i>Crotalus atrox</i>
Prairie rattlesnake – <i>Crotalus viridis</i>
Mojave rattlesnake – <i>Crotalus scutulatus</i>
Rock rattlesnake – <i>Crotalus lepidus</i>
Black-tailed rattlesnake – <i>Crotalus molossus</i>
Red diamond rattlesnake – <i>Crotalus ruber</i>
Speckled rattlesnake – <i>Crotalus mitchellii</i>
Sidewinder rattlesnake – <i>Crotalus cerastes</i>
Tiger rattlesnake – <i>Crotalus tigris</i>
Twin spotted rattlesnake – <i>Crotalus pricei</i>
Ridge nose rattlesnake – <i>Crotalus willardi</i>
Western rattlesnake – <i>Crotalus oreganus</i>

Table 33-2 Agkistrodon Species

US Copperheads and Moccasins
Northern copperhead – <i>Agkistrodon contortrix mokasen</i>
Osage copperhead – <i>Agkistrodon contortrix phaeogaster</i>
Southern copperhead – <i>Agkistrodon contortrix contortrix</i>
Broad-banded copperhead – <i>Agkistrodon contortrix laticinctus</i>
Trans-pecos copperhead – <i>Agkistrodon contortrix pictigaster</i>
Eastern cottonmouth – <i>Agkistrodon piscivorus piscivorus</i>
Florida cottonmouth – <i>Agkistrodon piscivorus conanti</i>
Western cottonmouth – <i>Agkistrodon piscivorus leucostoma</i>

As snakes are cold-blooded animals, snakebites generally occur in the warm months, with a particular increase in incidence in the spring and fall. The majority of snakebites occur in young men, with up to 60% of bites occurring in victims that were deliberately provoking the snakes.

2 Venom is produced in Duvernoy glands on the dorsal sides of the head (corresponding to parotid glands) enhancing the triangular appearance. During envenomation the venom is forced through the fangs by the palatine muscles. If a fang is broken off, it will be replaced by the next in a row of “proto-fangs.” Any clothing may limit the amount and depth of envenomation. The purpose of the venom is to immobilize or kill the prey and begin digestion. Pit viper venoms are complex – with up to 50 different proteins and enzymes identified.⁸⁻¹⁰ Over 90% of the dry weight of venom is proteinaceous in nature. Although it is common to classify the venoms as neurotoxic or digestive in nature, all snakes have varying compositions of venoms. The Crotalids will have a higher percentage of digestive/enzymatic type proteins than the Elapids, which will contain a higher percentage of neurotoxins. Common enzymes are phospholipases, metalloproteases, collagenase, and hyaluronidase (Table 33-4). These peptides and polypeptides act by damaging vascular endothelium and other cellular membranes. Complement is activated, fibrin is degraded, and platelets are activated. The increased permeability of the membranes leads to peripheral and pulmonary edema, hemorrhage, and hypotension. L-amino acid oxidase splits fibrinogen contributing to the induction of DIC. The Elapids in particular contain a higher percentage of proteins that block acetylcholine receptor sites. This can lead to dysphagia, slurred speech, seizures, coma, and death. Despite the very high toxicity of coral snake venom, only one fatality has been recorded in the United States in the past 50 years.

Table 33-3 *Sistrurus* Species

US Rattlesnakes – Genus <i>Sistrurus</i> (Ground Rattlers/Swamp Rattlers)
Massasauga – <i>Sistrurus catenatus</i>
Eastern – Subsp <i>catenatus</i>
Western – Subsp <i>tergeminus</i>
Desert – Subsp <i>edwardsii</i>
Western pigmy rattlesnake – <i>Sistrurus miliarius streckeri</i>
Carolina pigmy rattlesnake – <i>Sistrurus miliarius miliarius</i>
Dusky pigmy rattlesnake – <i>Sistrurus miliarius barbouri</i>

3 When evaluating the snakebite victim, it is important to document both local and systemic signs and symptoms. Vital signs should be recorded, and repeated at intervals guided by the clinical response. Pain, edema, and erythema at the site are common. Secondary symptoms include muscle twitching, perioral paresthesias, and a metallic taste in the mouth. Marking lines at the site of documented discoloration (Fig. 33-6) can help the clinician follow the progression of the envenomation. Swelling in the affected digit or limb should be measured (circumference) and followed closely. The amount of local tissue destruction is an accurate marker of the degree of envenomation. It is probable that if there is no pain or erythema by the time that the patient arrives in the ED, no envenomation has occurred. Intravenous access should be obtained. Laboratory evaluation should include a CBC with platelet count, PT, PTT, CPK, fibrinogen level, creatinine, BUN, and urinalysis. Up to 30% of Crotalid envenomations will show an abnormality in the coagulation profile, although clinical bleeding is exceedingly rare.¹¹ In Lovonas 2004 review of 400 copperhead bites from the Carolinas: no hypotension, no respiratory failure, and no deaths occurred.¹⁵ Eight patients did have laboratory abnormalities, but none developed bleeding complications. However, in severe envenomation by one of the larger rattlesnakes, diffuse capillary leakage can lead to pulmonary edema, hypotension, and shock.¹² A consumptive coagulopathy may rapidly develop. Such patients may bleed spontaneously from any site. Acute renal failure may result from direct nephrotoxins as well as myoglobinuria. An electrocardiogram, or at least continuous cardiac monitoring should be considered. If there appears to be no evidence of envenomation, the patient may be observed in the emergency department for several hours and discharged home. With evidence of envenomation our recommendation is for admission to the hospital, preferably a monitored bed, for observation and possible intervention for at least 24 hours.

Hyaluronidase
NAD-Nucleotidase
Factor-X activator
α-Fibrinogenase
Prothrombin activator
Collagenase
Elastase

Figure 33-6. Demarcation of hemolysis after bite.

As noted above treatment is largely dictated by the species of snake and the initial clinical presentation. Although a number of series have noted the appropriate treatment of *Agkistrodon* (copperhead and moccasin) bite is observation only,^{13–15} extrapolation of this data to rattlesnakes could be misleading. In the rattlesnake bite victim with a moderate or severe envenomation, early use of antivenom is appropriate, and should be strongly considered (see below). Although there are a number of snakebite severity indices (grading systems) published, a modification of the simple system proposed by Dart in 1996 is probably the most useful.¹⁶ A grade 1 envenomation is limited to the immediate bite site, a grade 2 envenomation extends onto less than a full extremity and may have non-life-threatening symptoms such as nausea, vomiting, mild tachycardia, and mild hypotension. A grade 3 envenomation involves more than an extremity and includes systemic signs such as severe hypotension/tachycardia or blood dyscrasias or clinically significant clotting abnormalities. Although enzyme-linked immunosorbent assays (ELISAs) have been developed that can directly measure serum venom antigens as well as identify the offending snake, clinical applicability of these types of tests are limited.¹⁷

Initial first aid on the scene should involve immobilization and splinting. Although there are no data to confirm this will limit the spread of venom, it might be more comfortable. The application of ice or heat seems to have little effect on results. A number of historical treatments should specifically be avoided. Incision and suction, advocated for years, is no longer recommended.¹⁸ A surgical incision in the field by a nonsurgeon can possibly involve vessels, tendons, and nerves and increase morbidity, and only a small amount of venom can actually be extracted with suction. Limited cooling of the extremity may have some benefit, although a version of this – ligation cryotherapy – is associated with a high rate of amputation.^{19,20} Although placement of a constrictor band may be of benefit in Australia (where Elapids predominate) to prevent rapid dissemination of a deadly neurotoxin, it is probably of little benefit in North America where the offending species is almost certainly a Crotalid. The use of a compression bandage has been shown to slow the systemic absorption of venom.^{21,22} This may make it the treatment of choice in the field for a nonnecrotizing envenomation, such as produced by an Elapid. It may however increase local necrosis when used to treat the bite of a pit viper.

The wound should be cleansed and the location of the puncture sites documented. The distance between the two fang marks is related to the size of the snake. The tetanus immunization status of the patient should be reviewed and updated. Steroids have no benefit in humans although these are often used by veterinarians.^{23,24} Steroids do have a role in treating the infrequent acute allergic as well as delayed-onset serum sickness that may occur after the use of sheep-derived antivenom, as noted below.

The prophylactic use of antibiotics has been evaluated by several studies and does not seem to reduce infection rates.^{25–28} Infection after snakebite is surprisingly uncommon and while patients are often given an antibiotic, there is no good clinical evidence for their use. Although many patients will have erythema, edema, and tissue necrosis and will appear infected, these are usually sterile; culture-proven infection occurring after snakebite should be treated appropriately. Culture of organisms in the mouth of the rattlesnake include *Pseudomonas*, *Enterobacteriaceae*, *Staphylococcus*, and *Clostridia*.²⁹

If the species is a coral snake or a nonindigenous Elapid, the administration of cholinergic agonists should occur at the first sign of symptoms. Calcium infusion may reduce the onset of seizures.

Certainly the most controversial decision point in management of snakebite is the administration of antivenom. Although hundreds of antivenoms are available worldwide for various species, for all practical purposes in North America we are only dealing with envenomation by Crotalids. Snakebite by coral snakes are uncommon, and while the venom is exceedingly toxic, the treatment is only supportive as antivenom is no longer available. Prior to 2000, the primary antivenom available in the United States for the bite of a Crotalid was a hyperimmune serum produced by envenomation of horses. Its use was associated with a high incidence of side effects: anaphylaxis, hypersensitivity, and delayed serum sickness.³⁰ In 2000, CroFab (Crotalidae Polyvalent Immune Fab [Ovine]) was introduced obviating the use of now unavailable horse serum products.^{12,31}

CroFab is truly an elegant drug. It is produced by immunizing sheep with the venom from the western diamondback rattlesnake (*Crotalus atrox*), the eastern diamondback rattlesnake (*Crotalus adamanteus*), the Mojave rattlesnake (*Crotalus scutulatus*) or the cottonmouth water moccasin (*Agkistrodon*). The monovalent immunoglobulin from the sheep is prepared by fractionation of the immunoglobulin from the serum, digesting it with papain, and then utilizing ion exchange and affinity chromatography to separate the Fab fragments specific to each species.³² The Fc portion of IgG is generally thought to be responsible for high rates of hypersensitivity and serum sickness seen with the

horse serum product developed by Wyeth in 1954, and hence this ovine (sheep) version is generally considered safer. The four different monospecific antivenins are then mixed (Table 33-5). In a murine model there is good antigenic crossover in treating other North American Crotalid envenomations.³³

Utilizing CroFab to treat Crotalid envenomation is somewhat controversial, primarily because of the cost/benefit ratio. The cost of this drug is a significant factor with wholesale prices up to \$2,000 per vial. Certainly any patient with life-threatening symptoms should immediately be given 4 to 6 vials of the antivenom.³⁴ Treatment is not based on the body mass of the patient – as the antivenom neutralizes the poison that is injected – this will vary with each envenomation. The lyophilized powder is reconstituted with 18 mL of normal saline, followed by dilution in 250 mL. Each dose is given over 1 hour. It is thought that venom is rapidly tissue bound, therefore the earlier the antivenom can be given, the more likely a favorable response. The packaging information states that treatment should begin within 6 hours of the bite. There is however at least one report of effective use of antivenom after significant delay.³⁵ Thus is the conundrum – there are certainly snakebites that initially appear innocuous that later become life-threatening. This has lead physicians in the emergency room to over treat large numbers of patients who do not require therapy, and why it is so important that every attempt be made to identity the offending species. If one can ascertain that the snake is one of the less virulent types (Agkistrodon or Sistrurus species) the patient can almost certainly be treated without the use of antivenom.^{14,36} However, in the patient with a deteriorating clinical condition, treatment should always be given. Repeated dosing should be given until clinical stability is achieved; although this is highly unlikely after 30 to 40 vials. The patient should be monitored for recurrence of symptoms and retreated if necessary.³⁷ CroFab has an estimated half-life of 12 to 23 hours.

Table 33-5 Components of Antivenom–CroFab Antibodies

LD50 Neutralizing Units
Crotalus atrox (Western diamondback) 1,350
Crotalus adamanteus (Eastern diamondback) 800
Crotalus scutulatus (Mojave rattler) 5,210
Agkistrodon piscivorus (Cottonmouth water moccasin) 460

LD50, median lethal dose.

Immediate adverse drug reactions will occur in 6% to 8% of patients.^{38,39} This may be related to the rate of infusion.⁴⁰ Although anaphylaxis would occur in up to 50% of patients treated with the older equine antivenin, it is an uncommon occurrence with CroFab – maybe up to 14% of patients.⁴¹ It should be treated aggressively when occurring: The antivenin infusion should be stopped and a combination of antihistamines (diphenhydramine), epinephrine, and steroids administered, depending on the severity of the response. The airway should be assessed and secured if necessary. Appropriate volume resuscitation should be instituted. Steroid dosing ranges from a single 125 mg intravenous bolus of methylprednisolone to short-course prednisone pulse dosing (60 mg daily for 5 days).⁴⁰

Serum sickness will occur in 13% to 16%^{39,41} of patients treated with ovine antivenom (CroFab), certainly less common than with the older Wyeth equine antivenom.³⁰ Serum sickness is a type III hypersensitivity reaction in which soluble antigen–antibody complexes are deposited diffusely in the presence of antigen excess. Symptoms such as urticaria, itching, nephritis, and arthralgia can occur for weeks after the infusion. The treatment for serum sickness is a pulse of corticosteroids tapered over 7 to 14 days.

There is no question that the purified ovine antivenin (CroFab) is much safer than the older horse product.^{8,42} This has led to some indiscriminate usage in emergency departments across the country. It should be recognized that the vast majority of snakebite victims will recover uneventfully with only supportive treatment. Each patient must be individually clinically evaluated and limit antivenom use to those in whom the potential benefits outweighs the risk of side effect.

CroFab has been used extensively in children as young as 14 months.^{43–45} There are beginning to be reports of overuse of CroFab in children as well as adults.⁴⁶ A special consideration should be use of antivenom in the pregnant patients. Certainly coagulopathy could be lethal to the mother and fetus. There have been limited reports of use of CroFab in pregnancy.⁴⁷ Reports of fetal loss of up to 20% are noted in the worldwide literature with snakebites of a variety of species. This seems to be improved with the use of antivenom.^{47,48} Certainly the risk/benefit ratio must be carefully weighed, but the general recommendation is to treat pregnant women with CroFab when indicated.

In the rare patient that develops clinical bleeding; such as hemoptysis, intracranial hemorrhage, or

gastrointestinal bleeding, correction of the coagulopathy should be undertaken with appropriate blood products. Antivenom should be given in these patients as initial therapy. Do not routinely treat thrombocytopenia or severe coagulopathy in the absence of bleeding. Coagulopathy can recur up to 2 weeks later.³⁷

Figure 33-7. Hemorrhagic bullae.

The use of surgery in the management of snakebite has a limited role. Although historically snakebite has been treated with various surgical procedures,^{19,49} it should be in an unusual patient that more than simple debridement is needed. Crosscut and aspiration of the puncture sites was utilized for years, but this is no longer recommended. Several studies have shown the limitations of this practice. In dogs, up to one-half of the venom can be removed if incision and suction are begun within 3 minutes.¹⁷ In rabbits up to 37% of antivenom can be removed. However, in human studies only about 11% of the venom may be removed.^{50,51} It is rapidly bound to tissues and is difficult to be removed by suction. Laceration of vessels and nerves by well-meaning people at the scene is likely to increase morbidity as well as increase the risk of infection. Both partial and radical surgical excision of the involved bite area has likewise been attempted with no proven benefit.⁵²⁻⁵⁵ A common finding is a local cytolytic response (Fig. 33-7), that produces a hemolytic bullae and requires debridement (Figs. 33-8 and 33-9). This can be expected to heal by secondary intention with a satisfactory cosmetic response (Fig. 33-10).

Another use of CroFab is in the patient with impending compartment syndrome. The great majority of snakebites deposit venom in the subcutaneous tissues, not subfascial. It can sometimes be difficult to differentiate a swollen painful extremity from a true compartment syndrome. When in doubt compartment pressures should be measured.^{55,56} With rising pressures (greater than 30 to 40 mm), antivenom therapy should be initiated (or repeated). With failure of response to adequate dosing of antivenom, appropriate surgical fasciotomy can save extremities. Prophylactic fasciotomy has no role in treatment. Stewart and colleagues at the University of Texas Health Science Center in San Antonio have an extensive experience with rattlesnake bites.⁵⁷ They have randomized animals to receive an intracompartmental injection of venom from the western diamondback rattlesnake. The animals received fasciotomy with debridement alone, antivenom alone, or antivenom with fasciotomy and debridement. Antivenom therapy prevented muscle loss and improved survival. Surgery alone did not. It was noted that muscle that had been debrided would have survived if treated with antivenom alone. Fasciotomy may increase the severity of local tissue loss.^{58,59} When fasciotomy is required because of rising compartment pressures that do not respond to antivenom, consideration for postoperative negative-pressure wound therapy should be given.

Figure 33-8. First debridement.

Figure 33-9. Second debridement.

Creative attempts at treating envenomation have even included the use of electrical current to neutralize the venom.⁶⁰ The use of current from the generator of an outboard motor and an automotive battery has even been attempted. As innovative and entertaining as these efforts may be, there is no improved outcome.⁶¹ The TASER® or conductive electrical weapon (stun gun) is a small hand-held device that produces a very high voltage with a low current. It is used primarily by law enforcement agencies to temporarily immobilize attackers. A group of physicians practicing in Ecuador reported a series of 34 patients in letters to the editor of *Lancet*.^{62,63} They claimed an immediate improvement with no mortality. The snakebites were most likely *Bothrops atrox* – the Fer-de-lance – a pit viper. Unfortunately this reported treatment was not a controlled study. Several animal studies have since proven electrical shock therapy to be ineffective in snakebite.⁶⁴⁻⁶⁶

Figure 33-10. Healed wound.

Special Consideration of Elapid Envenomation

As noted there are only three species of Elapids in the United States – the eastern coral snake, the Texas coral snake, and the Arizona coral snake. The Eastern coral snake (*Micrurus fulvius*) is found in the

southeastern United States up to Kentucky and North Carolina. The Texas coral snake (*Micrurus tener*) is found in west of the Mississippi across Arkansas, through Louisiana into eastern Texas. The Eastern and Texas coral snakes inhabit forests and shrubbery. The Arizona coral snake (*Micruroides euryxanthus*) is found in the desert climates of the southwestern United States into Mexico. Coral snakes are more active at night and hide under ground cover. Their behavior is elusive and they will generally try to flee when disturbed. This family of snakes has a common feature – bilateral upper maxillary fangs that are fixed into position and angled down and back. The fangs are grooved for instillation of the venom, which is predominately a neurotoxin. The snakes are oviparous and have round pupils. Their head is flat, with a smooth tapered tale and of course no rattles. They have characteristic coloration which is mimicked by several other nonvenomous species (such as the king snake and the scarlet king snake) in a biologic phenomenon referred to as Batesian mimicry.⁶⁷ Although the North American coral snakes are relatively small (less than 5 ft), some Elapids from other continents are very large; the Black mamba is 14 to 15 ft and the King Cobra can be up to 18 ft and weigh 25 lb. Although nonnative elapids bites have a substantial risk for death, only one known death from a Coral snake has occurred in the United States in the last 50 years (Bonita Springs Florida 2006).⁶⁸

The bite of an Elapid is likely to produce much less tissue injury than the bite of a Crotalid.⁶⁹ There may be minimal pain. Envenomation may result in immediate neurotoxicity (within 15 to 30 minutes in the case of the mamba or Australian brown snake) or be delayed a bit (2 to 5 hours with coral snakes). There is no longer any antivenom available for North American coral snakes, but local zoos may be able to provide antivenom for more exotic Elapidae. First aid should involve a compression bandage over the wound. The poison generally spreads by lymphatics; therefore field compression to occlude lymph flow at the site of envenomation can slow toxicity. Symptoms will be related to the neurotoxicity – confusion, muscle spasm, nausea, vomiting, and dizziness. Blurred vision and difficulty with speech will occur. Finally, respiratory paralysis of the diaphragm occurs with resultant death. Cardiovascular and pulmonary support is essential to salvage patients that progress to this state.⁷⁰ It should be noted that venom of an Elapid is incredibly toxic. The Taipan and Belcher sea snakes have an LD50 in mice of as little as 0.025 mg/kg of venom.⁷¹ Any suspected Elapid bite should be managed with the possibility of rapid demise of the patient. If the bite is of a nonnative Elapid, antivenom (if it can be found) should be administered promptly at the first sign of clinical demise. Death rates for untreated nonnative Elapids varies from 20% to 30% for cobras to nearly 100% for the mambas.⁷² Antivenom for exotic snakebites may be obtained from the local zoo or through their national organization – the Association of Zoos and Aquariums (<https://www.aza.org>) or through the Poison Control Center at 1-800-222-1222.

Figure 33-11. Gila monster.

Venomous Lizards

There are two venomous lizards in North America: the Gila monster (*Heloderma suspectum*) and the Mexican beaded lizard (*Heloderma horridum*). Both species have heavy bodies with large heads. The Gila monster is found in the southwestern United States, ranging primarily in Arizona, extending into southeastern California, southwestern Utah and New Mexico, and into northern Mexico. There are two subspecies: the banded Gila monster (Fig. 33-11) that is found in the northern portion of the habitat and the reticulated that exists in the southern portion of the range. It is the largest lizard in the United States with a length of up to 56 cm. The Gila monster has generated substantial lore in the southwestern United States, because of its characteristic appearance and apparent fetid breath. It lives below ground and spends most of its life in or near its burrow. It is primarily seen in the spring, in the morning hours during breeding season. It has powerful jaws and the bite is characterized by the tendency to hang on with the animal difficult to dislodge. The lizard has eight labial glands on either side of the lower jaw. The venom is secreted into the floor of the mouth where it is wicked into the victim via grooved lower

canine teeth. Envenomation is limited and deaths are virtually unknown.⁷³ The morbidity is usually secondary to local effects from the toxins present: serotonin, phospholipase A, amine oxidases, hyaluronidase, and proteases.⁷⁴ These produce pain at the site that usually resolves in less than 24 hours. Hypotension, coagulopathy, and myocardial infarction have been reported.⁷⁵ Nausea and vomiting can occur. Malaise may persist for several days. The patient should be admitted for observation and a low threshold for surgical exploration/debridement be given because the teeth often shed into the bite and can serve as a nidus for infection.⁷⁶

The Mexican beaded lizard is found from Sonora to Guatemala and is represented by four subspecies. They are larger than the North American Gila monster; with a maximum size of up to 91 cm. They have similar venom as the Gila monster and bites should be managed in a supportive fashion.

Insect Bites and Stings

4 Although the bite of a venomous snake will certainly draw more attention in the emergency department, in fact insects kill many more Americans (greater than 100 deaths per year)⁷⁷ than snakes (about 5 deaths per year). Although most of these deaths are from anaphylactic reactions, some are from overwhelming envenomation, particularly from those of the Africanized honey bee (the “killer” bee). Most of the treatment recommendations below are from expert opinion; few randomized trials have been performed.

Spiders

There are six genera of spiders in the United States that can produce painful bites, tissue necrosis, and rarely death. These fall into three groups – the brown recluse (Fig. 33-12), the black widow (Fig. 33-13), and the hobo spiders.⁷⁸

Figure 33-12. Brown recluse.

Brown Recluse

There are 13 species of *Loxosceles*, of which 5 have been known to produce tissue necrosis. Probably the species producing the most pathology is the brown recluse (*Loxosceles reclusa*). Envenomation by the hobo spiders (*Tegenaria agresis*) produces a similar wound. The brown recluse is generally found in the southern states.⁷⁹ Hobo spiders are found in the Pacific Northwest.⁸⁰ Bites from these two species generally are initially painless and the victim may not recall being bit. Pain and erythema develop over the next 6 hours. The venom can produce a painful, necrotic, slow healing wound over the next 48 to 72 hours.^{79,81} Two to 7 days after the bite an eschar develops with surrounding soft tissue induration. The eschar can conceal an underlying tissue necrosis that can persist for months.^{79,82} These can require extensive debridement leading to skin grafting and even amputation.

The venom is both hemolytic and cytotoxic. The enzyme that is thought to produce the “desmonecrotic arachnidosis” is sphingomyelinase D. The venom also contains hyaluronidase, lipase, arachidonic acid, and prostaglandins.^{83,84} Systemic symptoms occur in less than 10% of victims, more commonly in children. Rarely hemolysis, hemodynamic instability, and death have occurred.⁸⁵ Initial treatment should include analgesia, wound care, and tetanus prophylaxis. Antibiotics should be reserved for infection/cellulitis. Early debridement should be withheld. Consideration for oral dapsone therapy should be given. Dapsone is thought to work as an inhibitor of polymorphonuclear leukocyte chemotaxis. It has significant side effects and can produce hemolysis in G6PD-deficient patients. Its use is somewhat controversial. It has been shown to reduce the size of the skin lesion and lessen the amount of surgical debridement, but these are not prospective studies.⁸⁶ A controlled study of dapsone,

electroshock therapy and no treatment in guinea pigs showed some improvement with dapsone, but none with the electrical therapy.⁸⁷ Hyperbaric oxygen has been studied in rabbits and pigs and failed to demonstrate significant improvement.⁸⁸ A trial of hyperbaric oxygen, dapsone, and cyproheptadine in rabbits failed to show any improvement.⁸⁹ Systemic steroids and antihistamines likewise have not been shown to help. Initial surgical excision of the lesion has no clear benefit.⁹⁰ Delayed excision of the area of necrosis with skin grafting can be necessary. Recurrent necrosis in the same site can return even years later.

Figure 33-13. Black widow.

Black Widow Spiders

There are 31 species of the genus *Lactrodectus*, the Black Widow spider, of which 4 are found in North America. These are marked by a prominent red hourglass figure on the ventral aspect of the thorax. Although both the male and the female possess venom, only the bite of the female can penetrate human skin. The female is four times the size of the male. The female of the species is known for eating the male after mating, which may or may not occur. The bite may produce only minimal local symptoms, with only a small area of redness, or a “target” appearance. The venom contains alpha-latrotoxin, which is neurotoxic. This produces chest and abdominal pain, and the patient’s presentation may be confused as an acute surgical abdomen.⁹¹ Marked cramping and abdominal rigidity may be present. Fasciculations of facial muscles with ptosis and spasm may occur producing a particular facie. Hyperreflexia, paresthesia, cutaneous hyperesthesia, and nausea may also occur. Symptoms may occur within an hour and resolve over several days.⁹² The muscle spasm should initially be treated with benzodiazepines. Antivenin is available, and should be considered in the very young or ill patient. The dose is one ampule given in 50 mL of saline. The antivenom is equine and hypersensitivity testing should be done prior to giving the antivenom.^{93,94} A 1-mL test dose of horse serum is included with the antivenom for topical conjunctival testing. Calcium gluconate was often given in the past, but is no longer recommended. Mortality is exceedingly rare.

Hymenoptera

More than 100,000 species of Hymenoptera exist. This includes bees, wasp, hornets, and fire ants. The venom injected by these insects is at least as toxic as that of the rattlesnake, but the volume is much less. The venom is primarily a hemolysin and neurotoxin. Anaphylaxis is a common clinical problem produced by the envenomation. Approximately 0.4% of the human population is at risk of anaphylaxis from Hymenoptera stings.⁹⁵ The anaphylaxis is modulated by preformed IgE that activates mast cells leading to massive histamine release. This leads to laryngeal edema, pulmonary edema, and cardiovascular collapse. This must be treated aggressively with intravenous diphenhydramine and epinephrine as well as with management of the airway and supplemental oxygen. Most stings are mild, however, resulting in only dermal reactions – pain, erythema, and edema. The stinger should be removed and ice applied to the site. Application of meat tenderizer might be of some benefit. Patients with a history of insect sting anaphylaxis should be given a prescription for an epinephrine pen and be considered for venom immunotherapy. This is almost 100% successful in desensitization, but can take up to 3 years.

Killer Bees

Africanized honeybees (killer bees) are hybrids of the African honeybee and the European honeybee, the one commonly found in the United States. The Africanized honeybee was originally brought from Tanzania to Brazil in 1957, with the hope of better honey production. The bees have spread up through Central America, Mexico, and into Texas. They are continuing to advance at about 100 miles per

year.^{96,97} Africanized honeybees are indistinguishable from the European honeybee, so DNA (usually mitochondrial DNA) analysis is necessary to differentiate the subspecies.⁹⁸ They are termed “killer bees” because of increased aggressive traits. They show greater defensiveness of the hive, they have a bigger “alarm” area, and they deploy in greater numbers and will pursue perceived threats over much greater distances. Although their venom is of the same potency as the European bees, the number of stings received will usually be much greater. With more than 50 stings, nausea, vomiting, shock, hemolysis, rhabdomyolysis, coagulopathy, coma, and death may occur. Usually most patients will just complain of pain, but delayed toxic reactions – 6 to 48 hours – may also occur. It is recommended that any patient presenting with more than 50 stings be hospitalized and observed.⁹⁹ Laboratory evaluation with coagulation studies, platelet count, and liver function studies should be obtained.

Fire Ants

Fire ants are wingless members of the Hymenoptera order. They were brought to the United States from South America around 1918.¹⁰⁰ The red imported fire ants appear to have come over on a ship through Mobile, Alabama. Shipments of infested nursery stock and other agricultural products, natural mating flights, and floating on flood waters have contributed to their spread. Two species of imported fire ant now infect large areas of the Gulf Coast states.¹⁰¹ Fire ants aggressively attack any perceived danger to themselves or their mound.¹⁰² Each ant can produce multiple stings. The venom is a dialkylpiperidine that induces the release of histamine from increased mast cell reactivity. The fire ant sting produces a sterile pustule, which does not usually require antibiotic therapy. Infectious complications can occur at the site that may be more common in diabetic or immunocompromised individuals. Fire ant venom shares at least four antigenic proteins with bees and wasps. More than 80 fatalities have been reported from fire ant anaphylaxis, notably in Australia and southern United States. The treatment is the same as with bee/wasp sting anaphylaxis.⁷⁷

Scorpions

More than 1,500 species of scorpions can be found worldwide. Only about 20 or 25 are considered dangerous. They are in the class Arachnidia; close relatives of ticks, mites, and spiders. Their characteristic shape makes them readily identifiable. Scorpions prefer dry habitats but may be found throughout the southern United States. Scorpions are nocturnal, hiding during the day and becoming active at night. This behavior helps them manage their temperature and water balance, important for survival in their dry habitats. The scorpion's body has a 5-segmented tail that can be arched over the back and becomes more slender toward the end. On the end of the tail is the bulb-like poison gland/stinger. Between the last pair of legs are comb like structures called the pectines – sensory organs used to sense surface textures and detect prey. The venom toxicity varies greatly depending on the species, season, and age of the scorpion. Stings from dangerous species may cause paralysis, severe convulsions, cardiac irregularities, breathing difficulties, and death. In the United States most scorpion bites are not life-threatening and only result in local effects. In parts of Brazil, Mexico, North Africa, and Israel, however, the sting may be lethal. In Brazil the mortality rate is as high as 12% for adults and 60% in children.¹⁰³ In India, of 34 children admitted to a hospital for a scorpion sting, 14 had hypertension, 9 had acute pulmonary edema, 5 had a myocardial infarction, and 4 died.¹⁰⁴ Antivenins are typically available in area where dangerous species are found, either from a local zoo or state or university agricultural extension departments. One species in the North America is particularly venomous – the Arizona bark scorpion (*Centruroides sculpturatus*) (Fig. 33-14). The sting produces a dramatic neuromotor syndrome and respiratory insufficiency. It has produced several deaths in the United States and hundreds in Mexico. An antivenin is available in Mexico, but not in the United States.

Figure 33-14. Arizona bark scorpion.

Centipedes and Millipedes

There are approximately 3,000 species of centipedes in the world. They are arthropods with a single set of legs on each body segment. The front pair of legs are modified to deliver venom. One of the largest members of this class is the giant desert centipede (*Scolopendra gigantea*). It can grow to 26 cm in length. Significant morbidity, including EKG changes and rhabdomyolysis, can occur from centipede bites, but death is exceedingly rare. The most common symptoms include erythema, swelling, and pain.¹⁰⁵ Treatment is largely symptomatic, with reports of both ice and heat improving symptoms.¹⁰⁶ There are approximately 7,000 species of millipedes. They have 2 pairs of legs on each body segment. Millipedes do not have a mechanism to inject a venom, but instead secrete an irritating liquid from pores covering their body.¹⁰⁷ This can produce a superficial burn that is self-limiting. Only symptomatic therapy is indicated.

Asp Caterpillars

The asp is a venomous caterpillar found in the southern United States. It is the larval stage of the Southern Flannel Moth (*Megalopyge opercularis*) (Fig. 33-15). It has the appearance of soft furry ball, encouraging the unwary to touch it. The long hairs of the asp conceal shorter spikes that discharge venom. Typically an intense throbbing and pain occurs almost immediately. Erythematous spots occur at the site of envenomation. Symptoms include headache, nausea, vomiting, and the development of lymphadenopathy. Chest pain occurs occasionally. Rarely shock and respiratory distress have been reported. Death is exceedingly rare and is almost certainly because of a hypersensitivity reaction.¹⁰⁸⁻¹¹⁰ A similar caterpillar found in South America – *Lonomia* – has a death rate of 1.7%. The initial treatment should be to apply adhesive tape and pull it off to remove the spines. Ice packs and antihistamines may provide symptomatic relief. Intravenous calcium and steroids have been suggested as a treatment regimen.¹¹¹

Figure 33-15. Asp caterpillar.

Hypothermia

5 Humans will always attempt to maintain a constant body temperature despite changes in environmental temperature. Normal body temperature is 37°C sublingually, 38°C in the rectum, 32°C at the skin, and 38.5°C deep in the liver, with normal daily (circadian) variation of about 0.5°C to 1°C; we tolerate poorly even minor deviations from these norms.¹¹² Although humans have a remarkable capacity to dissipate heat by evaporating body water, our tropical evolutionary heritage has provided us with far less ability to cope with cold conditions. As a result, hypothermia can occur in a variety of clinical settings and from a number of causes (Table 33-6).

Table 33-6 Clinical Definitions of Hypothermia and Examples of Settings in Which They Occur

Type	Settings
Accidental	Recreational environmental exposure, cold-water immersion
Therapeutic	Treatment of Reye syndrome, cardio-pulmonary bypass, organ preservation
Drug induced	Alcohol, anesthetics, barbiturates, phenothiazines, morphine, other drugs
Central nervous system dysfunction	Transection of spinal cord, hypopituitarism, cerebrovascular accidents
Hypothalamic dysfunction	Wernicke encephalopathy, anorexia nervosa, head trauma, pinealoma, other tumors
Metabolic	Hypoglycemia, hypothyroidism, hypoadrenalism, malnutrition
Dermal dysfunction	Burns, erythrodermas
Traumatic	Occurs after any major injury

Adapted from Jurkovich GJ. Hypothermia in the trauma patient. *Adv Trauma* 1989;4:111–140.

Figure 33-16. Number of hypothermia-related deaths by year in the United States, 1979–2002. (After Hypothermia-related deaths —United States, 2003–2004. *MMWR Morb Mortal Wkly Rep* 2005;54:173–175.)

Hypothermia is considered to be present in humans if the core temperature drops below 35°C (95°F). Hypothermia is usually classified by temperature zones: mild (32°C to 35°C); moderate (28°C to 32°C); or severe (<28°C). Primary accidental hypothermia is defined as a decrease in core temperature that occurs as a result of overwhelming environmental cold stress, such as recreational misadventures that lead to cold-water immersion or prolonged environmental exposure. Secondary accidental hypothermia occurs in patients with abnormal heat production or thermoregulation, who become cold despite only mild cold stress. The most significant risk factors are advanced age, mental impairment, and substance abuse (alcohol, primarily), although hypothyroidism, hypoadrenalism, trauma, and hypoglycemia are other risk factors.^{113,114} Chronic hypothermia develops in patients with impaired heat generation (i.e., the elderly and infirm) who live in unheated apartments, are under continual cold stress, and after a time are found to have a chronically low temperature as if they have autoregulated to a new, lower-set core temperature.

A multicenter review of 428 cases of accidental hypothermia reported an overall mortality rate of 17%,¹¹⁵ although other reports document mortality rates as high as 80%, primarily a result of infection

and underlying illness. Treatment of accidental hypothermia remains highly variable. A report from an academic medical center in Amsterdam highlights this, as they reported that over an 8-year period (2000 to 2008) a total of 84 patients with accidental hypothermia were treated with 14 different rewarming techniques, with an overall mortality of 28.6%.¹¹⁶ It is estimated that each year about 1,500 patients in the United States have hypothermia listed on their death certificate, although the exact incidence of primary and secondary hypothermia and the associated morbidity and mortality remain uncharacterized.¹¹⁴ From 1979 to 2002, the CDC reported that a total of 16,555 deaths in the United States, an average of 689 per year (range 417 to 1,021), were attributed to exposure to excessive natural cold (Fig. 33-16).¹¹³ From 1999 to 2002, a total of 4,607 death certificates in the United States had hypothermia-related diagnoses listed as the underlying cause of death for an annual incidence of 4 per 1,000,000 population.¹¹³ Most reported hypothermia-related deaths (67%) occurred in males (Fig. 33-17), but the overall death rate is the same for both males and females. Notable is that deaths occur in all states, even those that generally are considered to have warm climates. Hypothermia-related deaths are reported by states with characteristically milder climates that experience rapid temperature changes and by western states that have high elevations and experience considerable changes from daytime to nighttime temperatures. States with the greatest overall death rates caused by hypothermia are Alaska, New Mexico, Wyoming, and Montana (Fig. 33-18).

Figure 33-17. Number and rate (per 100,000 population) of hypothermia-related deaths, by age group and gender, in the United States, 1979–2002. (After Hypothermia-related deaths United States, 2003–2004. *MMWR Morb Mortal Wkly Rep* 2005;54:173–175.)

6 The physiologic response to hypothermia is one of transitional changes, with few exact temperature-dependent responses (Fig. 33-19). Broadly speaking, the transition from a “safe zone” of hypothermia (in which physiologic adaptations to heat loss are working) to a “danger zone” of hypothermia (in which shivering is abolished, metabolism decreases, and heat loss is passively accepted) occurs between 33°C and 30°C. The initial effects of hypothermia mimic intense sympathetic stimulation, with tremulousness, profound vasoconstriction, tremendous increases in oxygen consumption, and acceleration of heart rate and minute ventilation.⁷⁷ When core body temperature cannot be measured, a four-stage hypothermia classification based on vital signs and level of consciousness has been developed by Swiss clinicians.^{114,117} It should be emphasized that the purpose of the Swiss clinical grading is to direct treatment in the absence of the ability to actually measure core body temperature, so it should have its primary purpose in the austere or field care environment.

The cardiovascular response to hypothermia begins with tachycardia, but followed by progressive bradycardia, which starts at approximately 34°C and results in a 50% heart rate decrease at 28°C. Cardiac output initially increases with the tachycardia, and then progressively decreases, with a concomitant fall in blood pressure. The conduction system is particularly sensitive to hypothermia: the PR interval, then the QRS complex, and finally the QT interval become progressively prolonged.¹¹⁸ As temperature falls below 30°C, atrial fibrillation, bradycardia, and ventricular dysrhythmia become common, with asystole occurring at temperatures below 25°C. Perhaps the most challenging management of an accidental hypothermia patient is the one with temperatures between 28°C and 32°C (Swiss stage 2), as these patients are prone to develop poorly perfusing arrhythmias, yet they often can be rewarmed with active external and environmental rewarming if such arrhythmias do not occur. Hence gentle manipulation of such patients is required. Because palpating pulses or measuring blood pressure in cold, stiff, hypothermic patients is difficult, the presence of an organized cardiac electrical rhythm should be taken as a sign of life that contraindicates cardiopulmonary resuscitation chest compressions, despite the absence of a palpable pulse. Such a rhythm may provide diminished but sufficient circulation in patients with severely reduced metabolism, and it is likely that vigorous chest

compressions will convert this perfusing rhythm to fibrillation. Rewarming should occur with close monitoring of rhythm, pulse, and blood pressure. If cardiac arrest occurs (Swiss stage 3 or 4), extracorporeal cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation (ECMO) for perfusion and rewarming is indicated.^{114,119,120} Among patients with what is likely Swiss stage 4, those treated with ECMO or CPB have a reported survival rate without neurologic impairment of 47% to 63%, compared to 37% for similar patients treated without active core rewarming and oxygenation techniques.¹¹⁴ One report noted excellent long-term functional outcomes in 15 of 32 young patients successfully rewarmed with CPB.¹¹⁹ All patients were intubated and ventilated and had received ongoing cardiac massage during transportation, and all 15 survivors had documented circulatory arrest (ventricular fibrillation or asystole) and fixed, dilated pupils. The mean interval from discovery of the patient to rewarming with cardiopulmonary bypass was 141 ± 50 minutes; the mean temperature was $21.8^{\circ}\text{C} \pm 2.5^{\circ}\text{C}$. A report from Finland documents a 61% (14 of 23) survival to hospital discharge for adults undergoing cardiopulmonary bypass after a mean of 70 minutes of cardiopulmonary resuscitation following hypothermic arrest primarily from cold-water immersion or exposure.¹²¹

Figure 33-18. Average annual rate per 100,000 of hypothermia-related deaths by state, 1999–2002.

Figure 33-19. Zones of hypothermia and corresponding physiologic responses. Wide biologic variability accounts for physiologic changes rarely occurring at the exact temperatures noted. (After Jurkovich GJ. Hypothermia in the trauma patient. *Adv Trauma* 1989;4:111–140.)

7 Respiratory drive is increased during the early stages of hypothermia, but below 33°C progressive respiratory depression occurs, resulting in a decrease in minute ventilation. This decrease is not usually a significant problem until temperatures below 29°C is reached. Occasionally, hypothermia results in the production of a large amount of mucus (cold bronchorrhea).¹²² This development predisposes to atelectasis and aspiration as ciliary action and the cough reflex are also depressed. Noncardiogenic pulmonary edema is also occasionally reported, especially in elderly patients and especially after prolonged periods of hypothermia.¹²³

The effect of core hypothermia on arterial blood gas interpretation warrants a comment. Arterial blood gas samples are typically warmed to 37°C before measurement. A nomogram of Severinghaus mathematical corrections is then used to estimate the blood gas values at the patient's actual body temperature. With each 1°C temperature reduction, the P_{CO_2} decreases by 4.4% and the P_{O_2} decreases by 7.2%. As an example, let's say a blood gas from a hypothermic 32°C patient is measured at 37°C showing a P_{CO_2} of 40 mm Hg and a P_{O_2} of 70 mm Hg; using the above correction techniques results in a reported P_{CO_2} of 32 mm Hg and a P_{O_2} of 48 mm Hg. The decrease in partial pressure is related to the increased solubility of gases in cold fluids and is not a result of a change in carbon dioxide content, oxygen content, or serum bicarbonate level. Clinicians often assume that the normal P_{CO_2} and P_{O_2} at 37°C are the values that should be attained at all temperatures. However, if normothermic endpoints for P_{CO_2} were attained in a hypothermic patient, they would have increased total-body CO_2 stores, which would manifest by a rising P_{CO_2} and a falling pH during rewarming. Likewise, attempts at increasing a P_{O_2} that reflects normal oxygen content at a lower temperature are also inappropriate. A far simpler strategy is to assess the blood gases at 37°C without temperature correction. Values that are normal and acceptable when reported at 37°C (without temperature correction) correspond to normal values and contents when "corrected" for hypothermic temperatures.

Temperature correction of blood gases for pH management is also unnecessary.¹²⁴ A pH of 7.40 at 37°C would be temperature corrected to 7.47 in a 32°C patient. At 37°C, the acid-base balance of water

is neutral (pH is equal to pOH) when the pH is 6.8, and the body functions optimally when its pH is offset 0.6 pH units above the neutral point of water and has a relatively alkaline pH of 7.40. The pH of water rises with cooling, causing the pH of blood to rise by 0.015 pH units/°C, without a change in bicarbonate content.¹²⁵ Treating a patient with a temperature of 30°C with a pH of 7.40 instead of 7.47 fails to maintain the normal pH offset above the neutral point of water (relative alkalinity) and results in an acidotic cellular and chemical environment that has a multiplicity of effects on enzyme systems. Because blood with a pH of 7.40 assessed at 37°C is reported as having a pH of 7.47 when temperature corrected to 32°C, the simplest strategy when confronted with a patient with a temperature of 32°C is to assess the blood gas at 37°C only and to use the 37°C uncorrected pH value for management.^{126–128}

The neurologic response to hypothermia is heralded by progressive loss of lucidity and deep tendon reflexes and, eventually, by flaccid muscular tone. Patients are often amnestic below 32°C, and between 31°C and 27°C they usually lose consciousness. Pupillary dilatation and loss of cerebral autoregulation occur at temperatures below 26°C, and electroencephalography becomes silent at 19°C to 20°C.¹²⁹ These findings, combined with an unobtainable pulse and apparent rigor mortis, may cause the patient to appear dead. It is important to remember that patients have been revived from core temperatures as low as 14°C¹³⁰ and hence the saying “No one is dead until warm and dead.”¹³¹ An exception to this admonition probably includes the patient who has sustained an anoxic event while still normothermic and has a serum potassium level greater than 10 mmol/L, although the Bernese criteria for trauma and hypothermia have picked a level of 12 mmol/L as being nonsalvageable.^{114,117,121,132} The role of hypothermia in brain death determination remains controversial. Brain death is a medically and legally accepted mechanism of death in the United States and worldwide. Yet significant variability in individual institutional policies regarding the determination of brain death occurs. In 2010 the American Academy of Neurology (AAN) issued guidelines on the determination of brain death.¹³³ A recent study examined how well 52 organ procurement organizations and 508 unique hospitals have adopted these guidelines, determining that among other variables in policy, only 181 of 228 policies (80%) required the absence of hypothermia (temperature >36°C) in brain death determination.¹³⁴

In classic surgical physiology research, Moyer and DeBakey showed that with hypothermia, reduction in blood pressure and cardiac output decreases glomerular filtration rate, but urinary output is maintained because of impairment in renal tubular Na⁺ reabsorption (cold diuresis).^{135,136} Vasoconstriction also results in an initial increase in central blood volume that prompts a diuresis. Ileus, bowel wall edema, depressed hepatic drug detoxification, punctate gastric erosions (Wischnevsky ulcers), hyperamylasemia, and, rarely, hemorrhagic pancreatitis are hallmarks of the intestinal response to hypothermia. Hypothermia inhibits insulin release and insulin uptake at receptor sites, making hyperglycemia a relatively common finding, especially at temperatures below 30°C.¹³⁷ Exogenous insulin administration is unwarranted because it may result in rebound hypoglycemia during rewarming. Serum electrolyte changes are unpredictable, but serum potassium is often slightly increased in hypothermic patients because of renal tubular dysfunction, acidosis, and the breakdown of liver glycogen.¹³⁸ Hypothermia also appears to affect endothelial cell adhesion molecule function, which may partially explain increased infectious complications in hypothermic patients.¹³⁹ One study demonstrated a drop of 1.9°C core hypothermia triples the incidence of surgical wound infection following colon resection and increases the duration of hospitalization by 20%, leading to the now standard perioperative checklist monitoring of body temperature during surgery.¹⁴⁰

Body temperature has a significant effect on oxygen uptake. Oxygen consumption (VO₂) initially increases dramatically with any fall in body temperature. When involuntary muscle contractions in the form of shivering occur, oxygen consumption increases by as much as three- to fivefold.^{141,142} This process is inefficient because shivering produces heat near the surface of the body, causing most of the heat to be lost to the environment, with less than 45% being retained by the patient. As core temperatures fall to between 33°C and 30°C, shivering is abolished, and the patient will rapidly sink to ambient temperature.

The thermoregulatory drive is such a powerful one that it takes precedence over many other homeostatic functions. The resultant increase in oxygen utilization may result in anaerobic metabolism, acidosis, and significant cardiopulmonary stress. One study noted a 35% increase in oxygen consumption and a 65% increase in CO₂ production in postoperative patients after resolution of anesthesia, when the thermostatic drive reappeared.^{143,144} In another study, a core temperature decrease of as little as 0.3°C in postoperative patients was associated with a 7% increase in VO₂, and temperature reductions between 0.3°C and 1.2°C were associated with a 92% increase in VO₂, with proportional increases in minute ventilation. Shivering can be iatrogenically abolished with low doses of

meperidine (Demerol®) and possibly ondansetron (Zofran®, Zuplenz®). Further details of the specific organ system responses to hypothermia are beyond the scope of this chapter, but the interested reader is referred to several excellent indepth monographs.^{112,145,146}

Hypothermia in Trauma Patients

Mild hypothermia is very common after traumatic injury. The thermoneutral environment for humans is a humid and warm 28°C (82.5°F) (think tropical islands). When ambient temperature falls below the thermoneutral temperature (i.e., the temperature at which no thermogenesis or heat dissipation is necessary), an increase in heat production is required to maintain a normal body temperature. Combustion is the only source of endogenous heat production, and this process requires an increase in oxygen utilization. After shock or injury, however, oxygen supplies are often limited and further heat loss occurs owing to cold emergency department and operating room environments, cold fluid resuscitation, and open thoracic and abdominal cavities. Anesthetic and neuromuscular blocking agents that prevent the heat-producing shivering response further aggravate this. Thus, the occurrence of hypothermia in surgical or critically injured patients is most often a form of secondary accidental hypothermia.

One study found that 57% of trauma patients admitted to a level 1 trauma center were hypothermic at some time and that temperature loss was most significant in the emergency department.¹⁴⁷ Another study reported that the average initial temperature for 94 intubated major trauma victims was 35°C, with no seasonal variation.¹⁴⁸ Of patients in this study, 66% were hypothermic on admission; 43% were mildly hypothermic (34°C to 36°C), and 23% had temperatures below 34°C. Likewise, Jurkovich and Luterma reported that 42% of 71 adult trauma victims with an injury severity score (ISS) of 25 or higher had core temperatures below 34°C and in 13% the core temperature fell below 32°C.¹⁴⁹ Importantly, there were no survivors when core body temperature was below 32°C. Inaba reported that of 118 patients requiring emergent surgery following traumatic injury, hypothermia (<35°C) was present in nearly 30% of patients upon presentation to the operating room, and that a continued decrease in core temperature was associated with increased mortality. This mortality rose to 50% if temperature fell below 32°C.¹⁵⁰ Both mortality rate and the incidence of hypothermia increase with higher ISS, massive fluid resuscitation, and the presence of shock, but controlling for these variables still demonstrates that the mortality rate of the hypothermic trauma patient is greater than that of the warm trauma patient.¹⁵¹ Although the mortality rate for moderate (28°C to 32°C) degrees of primary accidental hypothermia is approximately 20%,^{114,115} moderate levels of hypothermia in trauma and critically ill patients are associated with a much higher mortality rate. Rutherford et al.¹⁵² reported that 9.4% of surgical intensive care unit patients had a core body temperature less than 35°C; the mortality rate of the hypothermic trauma patients was 53%. In fact, compared with other patient populations, the mortality rate associated with hypothermia in the trauma victim is so high that the definition of mild, moderate, and severe hypothermia in the trauma patient warrants special classification (Table 33-7).¹¹²

CLASSIFICATION

Table 33-7 Zones of Severity for Hypothermia

Zone	Temperature
Mild hypothermia	36°C–34°C (<96.8°F–93.2°F)
Moderate hypothermia	34°C–32°C (<93.2°F–89.6°F)
Severe hypothermia	<32°C (<89.6°F)

Hypothermia appears to occur primarily in victims of relatively severe trauma. Little and Stoner,¹⁵³ while reporting on a heterogeneous group of 82 trauma patients, observed that hypothermia occurred only in those patients with an ISS greater than 12. Skin temperature fell from 32.0°C to 31.7°C, whereas core temperature fell from 37.3°C to 36.5°C. Hypothermia did not occur in less severely injured patients, and shivering, which should be expected, was noted in only one of the hypothermic patients. Mild degrees of injury have, in fact, been associated with small elevations in core body temperature, particularly when the shivering response mechanism has not been abated.^{112,154} It is notable that over the past two decades, considerable attention has been given to preventing hypothermia in trauma patients. Prior to the 1993 version of Advanced Trauma Life Support, the student and instructor course books did not include the prevention of hypothermia in the primary survey. The recognition that hypothermia can be prevented has resulted in substantial changes in the management of the acute

injured patient. As a result, the “lethal triad” of coagulopathy, acidosis, and hypothermia is much less frequently observed.¹⁵⁵

The detrimental effect of hypothermia in the human trauma victim is contrasted by a large body of experimental evidence in animals suggesting that hypothermia has a protective role in shock. This extensive body of literature is reviewed elsewhere,¹¹² but in general, animals subjected to combined hypothermia and shock (hemorrhage, burn, and blunt trauma) usually survive longer than similarly injured but actively warmed animals. Blalock and Mason (1941) were among the first in modern times to recognize the ability of hypothermia to prolong survival times after shock,¹⁵⁶ but they emphasized that the overall survival rate was unchanged, an observation reaffirmed in 2003.¹⁵⁷ However, increases in both survival times and survival rates have been shown in a number of animal models of induced hypothermia after hemorrhagic shock.^{158,159} The protective effects of hypothermia in preventing ischemia–reperfusion injury have been described in a number of models, including muscle, intestine, and rabbit ear.^{160–162} These observations have prompted some to suggest that there is a role for iatrogenic-induced hypothermia in severe trauma patients, with the goal being a reduction of oxygen consumption in the setting of limited oxygen delivery (hypovolemic shock) to allow surgeons time to repair injured structures and then rewarm and resuscitate the patients.^{163–165}

Hypothermia has also been utilized in attempts to protect the traumatically injured brain. The use of therapeutic hypothermia in a patient with traumatic brain injury was first reported in 1943¹⁶⁶ and sporadically over the ensuing 2 decades¹²⁰ in 2001, Clifton et al. reported a randomized, multicenter, controlled trial of core body hypothermia in trauma patients with severe closed head injury.¹⁶⁷ Select trauma patients (GCS 3 to 7) were intentionally cooled within 6 hours of injury to 32°C to 33°C for 48 hours after injury and then rewarmed. The outcome was poor (defined as severe disability, a vegetative state, or death) in 57% of the patients in both groups. Mortality was 28% in the hypothermia group and 27% in the normothermia group ($p = 0.79$). The patients in the hypothermia group had more hospital days with complications than the patients in the normothermia group. This study has led most authorities to conclude that treatment with total-body hypothermia is not effective in improving outcomes in patients with severe brain injury. Other authors have also reported higher rates of pneumonia and diabetes insipidus in patients with severe head injury and induced hypothermia.¹⁶⁸ Evidence further supporting the harmful effect of hypothermia in the trauma patient is provided by a prospective, randomized trial of rapid rewarming versus conventional rewarming of 57 multiple-trauma patients.¹⁶⁸ In this study, trauma patients who were rapidly rewarmed with continuous arteriovenous rewarming (CAVR) from less than 34.5°C to greater than 36°C required less resuscitation fluid volume and had a lower early mortality rate than those rewarmed more slowly. Failure to rewarm in either group was uniformly fatal. The survival rate at 3 days after injury was 82% in the rapid rewarm group versus 62% in conventionally managed patients. Approximately 50% of the patients in both groups had a severe head injury, defined as a head abbreviated injury severity score of 3 or greater. In this well-controlled study, maintenance of hypothermia not only failed to confer an advantage but also was detrimental to early survival.

The use of hypothermia in the treatment of acute cardiac arrest is beyond the scope of this chapter. It is discussed in [Chapter 20](#). However, the principle of this increasingly common technique is the same as the principle of organ preservation for transplantation – cooling of the body decreased oxygen consumption and may allow for a longer period of relative anoxia with good recovery.^{169–171} The advantage in these patients, or rather the difference between the acute care arrhythmia patient and the patient with trauma is likely the total-body tissue injury and its effect in coagulation and the inflammatory response. But the attraction for the concept of “suspended animation” with induced hypothermia in trauma remains seductive.

The role of hypothermia in the injured patient remains complex. It is apparent that the physiologic consequence of severe trauma is a drop in core body temperature, either as a protective response to shock or the result of diminished heat production caused by failing metabolism. The frequent presence of lactic acid accumulation in cold, seriously injured patients supports the latter hypothesis. Clinical studies indicate that even mild hypothermia in the trauma patient is predictive of a poor outcome, given our current capabilities of surgical repair of injured organs. Hypothermia does diminish metabolic demands and oxygen consumption, but the price appears to be malfunction of enzymes and physiologic systems necessary to recover from injury.

The systems most affected by hypothermia in victims of injury are those involved in clotting. Focused attention on the coagulation mechanisms in trauma patients over the past decade has exposed the lack of a comprehensive understanding of the complex relationship between injury, inflammation, and

coagulopathy.¹⁷² Temperature is yet another variable in this complexity. Reports of coagulation abnormalities in patients with apparently normal clotting factor levels surfaced shortly after the introduction of hypothermic cardioplegia for cardiac surgery.^{173,174} Although hemodilution with volume expanders deficient in clotting factors and platelets is the usual cause of nonsurgical bleeding, cold platelets are known to undergo morphologic changes that affect adherence, including loss of shape, cytoplasmic swelling, and dissolution of cytoplasmic microtubules necessary for normal motility.¹⁷⁵ Platelet activation is also associated with activation of cell membrane phospholipases that hydrolyze phospholipids to arachidonic acid, a precursor to prostaglandin endoperoxides and thromboxane A₂, a potent vasoconstrictor necessary for normal platelet aggregation.¹⁷⁶ Valeri et al.¹⁷⁷ induced systemic hypothermia to 32°C in baboons, but kept one forearm warm using heating lamps and a warming blanket. Simultaneous bleeding time measurements in the warm and cold arm were 2.4 and 5.8 minutes, respectively. This effect, which was reversible with rewarming, appeared to be mediated by cold-induced slowing of the enzymatic reaction rate of thromboxane synthetase, which resulted in decreased production of thromboxane A₂. Bleeding observed at mildly reduced temperatures (33°C to 37°C) results primarily from a platelet adhesion defect and not reduced enzyme activity or platelet activation; however, at temperatures below 33°C, both reduced platelet function and enzyme activity likely contribute to the coagulopathy,¹⁷⁸ perhaps helping to explain why 32°C is such a critical temperature in the coagulopathic injured patient.

As with blood gases, clinical tests of coagulation are temperature standardized to 37°C. Fibrometers contain a thermal block that heats the plasma and reagents to 37°C before initiating the assay. Thus, tests of coagulation reflect clotting factor deficiencies but are corrected for any potential effect of hypothermia on clotting factor function. A detailed study of the kinetic effects of hypothermia on clotting factor function has been undertaken by Reed et al.¹⁷⁹ He performed clotting tests (PT, PTT, and thrombin time) on reference human plasma—containing normal clotting factor levels at temperatures ranging from 25°C to 37°C. The results showed a significant slowing of all coagulation tests at temperatures below 35°C that was proportional to the degree of hypothermia. The prolongation of clot formation occurred at clinically relevant levels of hypothermia and was equivalent to that seen in normothermic patients with significant clotting factor depletion. For example, assays conducted at 35°C, 33°C, and 31°C prolonged the PTT to the same extent as would occur in a euthermic patient with reductions in factor IX levels to 66%, 32%, and 7% of normal, respectively.

Clotting factor supplementation is not the answer to a hypothermia-induced coagulopathy; rewarming is. However, in many seriously injured patients, clotting factor depletion exists in conjunction with hypothermia. A potentiating effect of hypothermia on coagulation dysfunction occurs in plasma of patients with deficient clotting factor levels, although there does not appear to be synergy between the two conditions.¹⁸⁰ Hypothermic, coagulopathic trauma patients still benefit from coagulation profile testing. If prolongation of PT and PTT is evident in plasma warmed to 37°C, clotting factor replacement is indicated. If PT and PTT are near normal, rewarming alone reverses the clinically apparent coagulopathy.

Treatment

8 Rewarming techniques are usually classified as passive external rewarming, active external rewarming, or active core rewarming.¹⁸¹ Passive external rewarming simply implies allowing spontaneous rewarming to occur with the patient removed from a hypothermic environment and is usually used only for the mildly hypothermic patient. Active external rewarming techniques include surrounding the patient with warm blankets or heating pads, infrared heating lights, and immersion in warm water. Active core rewarming includes heated intravenous fluids, as well as heated peritoneal or thoracic lavage; heated gastric, bladder, or colonic lavage; heated and water-saturated inhaled air; and extracorporeal circulatory rewarming. Blood rewarming is currently limited to a maximum temperature of 42°C by the American Association of Blood Banks, but rewarming to 49°C with inline microwave blood rewarmers has been reported as safe, as has intravenous fluid rewarming to 65°C.^{182,183}

The advantages and disadvantages of each technique are regularly debated, particularly regarding the role of external versus core rewarming. It is clear, however, that the rate of heat transfer to the hypothermic patient is greatest using active core rewarming, particularly extracorporeal circulation rewarming. This may be a critical factor in surgical patients for whom rapid restoration of clotting and cardiac function is necessary.

The technique of rewarming the hypothermic victim by extracorporeal circulation has been described by numerous authors, initially based on small personal experiences and using cardiopulmonary bypass

techniques of open-heart surgery.^{119–121} This technique has appeal in cases of primary accidental hypothermia, in which maintenance of circulation, correction of hypoxia, and replenishment of intravascular volume may play a role as large as correcting the temperature change itself. The need for systemic anticoagulation has, however, generally limited the usefulness of full cardiopulmonary bypass rewarming in the trauma patient. More recently the use of ECMO for core hypothermia rewarming has been the subject of numerous publications as more centers become more experienced with this tool.¹⁸⁴

A simplified technique of extracorporeal active core rewarming is CAVR.¹⁸⁵ This technique makes use of the patient's own blood pressure to drive an extracorporeal circuit through an efficient, but small countercurrent heat-exchange device. Systemic anticoagulation is not necessary if the tubing is heparin-bonded and trauma patients are relatively anticoagulated. The relative ease of use made this device widely applicable in rewarming severely hypothermic patients with an intact circulation and, in a prospective, randomized trial of rewarming trauma patients, demonstrated its efficacy by improved survival.¹⁶⁸ Unfortunately, the product used in that referenced study by Gentilello et al. is no longer in commercial production.

Direct intracirculation rewarming can be accomplished with commercially available devices that employ either an intra-vena caval countercurrent heat-exchange device (InnerCool RTx®, Phillips Healthcare, Best, The Netherlands) or balloon catheters with large surface areas (Alsios/Zoll Medical Irvine, CA). The ownership and design of these devices change rapidly, as the clinical need is limited. Although initially developed to cool patients for neurosurgical procedures, they are now used primarily for inducing and maintaining hypothermia following sudden cardiac arrest; rewarming can be accomplished by simply changing the temperature of the closed-loop circulating fluid. Requirements are the commercial bedside console and the specialized endovascular temperature control catheter, inserted via the femoral vein to the vena cava, usually with a larger size introducer (10 to 12 Fr). Data on rewarming cold patients suggest that rewarming can occur up to 3°C per hour compared to 6°C to 9°C per hour with ECMO or CPB.^{114,186}

The use of body cavity lavage with warm solutions is a simple, less invasive method of accomplishing active core rewarming; however, rewarming rates with body cavity lavage vary greatly based on initial core temperature, dialysate temperature, infusion rate, and dwell time. Several studies support the notion that active core rewarming by peritoneal lavage is preferable to active external rewarming.¹⁸⁷ Moss examined three techniques of rewarming hypothermic and cardiac-arrested dogs, concluding that both peritoneal lavage (55°C dialysate) and partial extracorporeal circulation were faster than active external rewarming with a heating blanket.¹⁸⁸ A frequently stated disadvantage of external rewarming is that the peripheral tissues are rewarmed in advance of the still cool “core,” resulting in peripheral vasodilation. In the presence of inadequate volume resuscitation, this rewarming method may result in vascular collapse (“rewarming shock”) and a subsequent fall in central temperature (“afterdrop”) as the cold peripheral blood returns to the core. Whether this process is the mechanism of the core afterdrop is debatable because a core afterdrop has been noted to occur in animal models even during complete circulatory arrest. Volume contraction caused by vasoconstriction, cold diuresis, and cellular swelling coupled with inadequate fluid resuscitation may be a more appropriate explanation for circulatory collapse during rewarming.

The thermodynamic principles of heat transfer to the hypothermic patient are reviewed in greater detail elsewhere, but a sense of rewarming rates and quantity of heat transferred by various techniques is instructional.^{181,189} Ventilating a patient with a core temperature of 32°C with water-saturated air at 41°C results in a maximum heat transfer rate of 9 kcal/hr. For comparison, basal metabolic heat generation produces approximately 70 kcal/hr, and shivering produces up to 250 kcal/hr. Given the specific heat of the body (0.083 kcal/kg/°C), 58 kcal is required to raise the temperature of a 70-kg patient by 1°C. Thus, more than 6 hours would be required to warm a 32°C patient using 41°C humidified inspired air.

Heat transfer rates using body cavity lavage can be similarly calculated based on the specific heat of water (1 kcal/kg/°C). If 1 L of 44°C water infused into a body cavity dwells long enough to exit at 40°C, 4 kcal of heat will have been transferred to the patient. Thus, over 14 L of fluid is needed to increase core temperature by 1°C. However, warming becomes less efficient as the patient rewarms because a longer dwell time is required to reduce the temperature of the infusate to 40°C.

Warming by cardiopulmonary bypass or ECMO or CAVR is the most efficient method of core heating. With flow rates of 15 to 30 L/hr, it is possible to deliver 120 to 240 kcal/hr if the reinfused blood is heated to 40°C, a rate of heat transfer over 10 times that of the other methods. In any case, the urgency with which rewarming must be accomplished depends on how adversely the hypothermia is affecting

the patient. With the exception of extracorporeal circulatory methods, most rewarming techniques serve primarily to prevent loss of endogenously generated heat and are ineffective in circumstances in which rapid rewarming is indicated. Early and direct attention to preventing heat loss is therefore essential in surgical patients. With more widespread adoption of ECMO capabilities for treating severe lung disease, centers are starting to report on the use of this modality as a rewarming technique. The combination of injury and hypothermia represents a particular challenge. Swiss physicians with experience in treating injured and hypothermia avalanche victims have developed the Bernese Hypothermia Algorithm, a detailed approach to rewarming techniques and injury care priorities in this population.¹⁹⁰

Cold Injury and Frostbite

9 Frostbite is a cold injury limited to digits, extremities, or exposed surfaces that is the result of direct tissue freezing. Chilblain (aka *pernio*) and trenchfoot are the result of more chronic exposure to an environment just above freezing. Both of these types of cold injury have been a major cause of morbidity during war experiences. They resulted in more than 7 million lost soldier fighting days by Allied forces in World War II and were reportedly the most common major injury sustained by British soldiers in the Falklands expedition.¹³⁸

The terms *chilblain* and *pernio* describe a form of local cold injury characterized by pruritic, red-purple papules, macules, plaques, or nodules on the skin. The lesions are often associated with edema or blistering and are caused by a chronic vasculitis of the dermis¹⁹¹; this entity does not appear to be related to hereditary protein C or S deficiency.¹⁹² This pathologic process is provoked by repeated exposure to cold, but not freezing, temperatures. This injury typically occurs on the face, the anterior surface of the tibia, or the dorsum of the hands and feet, areas poorly protected or chronically exposed to the environment. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Treatment consists of sheltering the patient, elevating the affected part on sheepskin, and allowing gradual rewarming at room temperature. Rubbing and massage are contraindicated because they can cause further damage and secondary infection.

Trench foot or cold immersion foot (or hand) describes a nonfreezing injury of the hands or feet, typically in sailors, fishermen, or soldiers, that is caused by chronic exposure to wet conditions and temperatures just above freezing.¹⁹³ It appears to involve an alternating arterial vasospasm and vasodilatation, with the affected tissue first cold and anesthetic and then hyperemic after 24 to 48 hours of exposure. With the hyperemia comes an intense, painful burning and dysesthesia, and tissue damage is characterized by edema, blistering, redness, ecchymosis, and ulceration. Complications of local infection or cellulitis, lymphangitis, and gangrene may occur. A posthyperemic phase occurs 2 to 6 weeks later and is characterized by tissue cyanosis with increased sensitivity to cold. Treatment is best started during or before the reactive hyperemia state and consists of immediate removal of the extremity from the cold, wet environment with exposure of the feet (or hands) to warm, dry air. Elevation to minimize edema, protection of pressure spots, and local and systemic measures to combat infection are indicated. Massage, soaking of the feet, or rapid rewarming is not indicated. Demyelination of nerves, muscle atrophy, fallen arches, and osteoporosis may all present long-term complications, and a tendency toward marked vasospasm during subsequent exposure to cold develops in some patients.¹⁹⁴

Frostnip is the mildest form of cold injury. It is characterized by initial pain and pallor, with subsequent numbness of the affected body part. Skiers and other winter outdoor enthusiasts are most likely to experience this cold injury to the nose, ears, or tips of digits. The injury is reversible and warming of the cold tissue results in return of sensation and function with no tissue loss.

Frostbite is a more severe and common form of cold injury. Frostbite damage is caused by direct ice crystal formation at the cellular level with cellular dehydration and microvascular occlusion. Frostbite is traditionally classified into four grades of injury severity (Table 33-8).

The affected body part nearly always initially appears hard, cold, white, and anesthetic, regardless of the depth of injury. Because the appearance of the lesion changes frequently during the course of treatment and because the initial treatment regimen is applicable for all degrees of insult, some authorities suggest discarding this classification as a prognostic impossibility and simply classifying frostbite as either superficial or deep.¹⁹⁵

Weather conditions, altitude, degree of protective clothing, duration of exposure, and degree of tissue wetness are all contributing external factors to the development of frostbite injury. Because sensory nerve activity is abolished at 7°C to 9°C, the disappearance of pain is an early warning sign of cold injury. Acclimation to cold may be protective, whereas a previous history of frostbite probably

predisposes to another cold tissue injury. Smoking and a history of arterial disease also are contributing factors. In urban environments, more than 50% of frostbite injuries are alcohol-related and in one report, 16% of these patients also had a significant underlying psychiatric illness.¹⁹⁶

Evidence suggests that frostbite injury has two components – the initial freeze injury and a reperfusion injury that occurs during rewarming. The initial response to tissue cooling is vasoconstriction and arteriovenous shunting, intermittently relieved (every 5 to 7 minutes) by vasodilation, the so-called hunting response.¹⁹⁷ With prolonged exposure, this response fails, and the temperature of the freezing tissue approximates ambient temperature until -2°C . At this point, extracellular ice crystals form, and as these crystals enlarge, the osmotic pressure of the interstitium increases resulting in movement of intracellular water out of cells and into the interstitium. Cells begin to shrink and become hyperosmolar, disrupting cellular enzyme function. If freezing is rapid ($>10^{\circ}\text{C}/\text{min}$), intracellular ice crystal formation will occur, resulting in immediate cell death.¹⁹⁸ In addition, endothelial cell disruption and red cell sludging associated with freezing result in cessation of circulation.

CLASSIFICATION

Table 33-8 Classification of Frostbite

Degree	Description of Frostbite
First	Tissue freezing with hyperemia and edema but without blistering
Second	Tissue freezing with hyperemia, edema, and characteristic large, clear blisters
Third	Tissue freezing with death of subcutaneous tissues and skin, resulting in hemorrhagic vesicles that are in general smaller than second-degree blisters
Fourth	Tissue necrosis, gangrene, and eventual full-thickness tissue loss

During rewarming, red cell, platelet, and leukocyte aggregation occurs and results in patchy thrombosis of the microcirculation. These accumulated blood elements are thought to release, among other products, the toxic oxygen free radicals and the arachidonic acid metabolites PGF_{2a} and thromboxane A_2 , which further aggravate vasoconstriction and platelet and leukocyte aggregation.^{199,200} However, the exact mechanism of tissue destruction and death after freeze injury remains poorly defined. Animal studies suggest that vascular injury in the form of endothelial cell damage and subsequent interstitial edema, but not vessel thrombosis, predominate as initial events in rewarming injury.²⁰¹ A substantial component of severe cold injury may be neutrophil mediated, as suggested by the observation that a monoclonal antibody to neutrophil–endothelial and neutrophil–neutrophil adherence can markedly ameliorate the pathologic process of a severe cold injury.²⁰² In this rabbit model, animals treated with anti-CD11/CD18 adhesion molecule after cold injury (30 minutes at -15°C) but before rewarming (39°C water bath) had significantly less tissue loss and edema. The implication of these observations is that much of the injury of severe frostbite occurs during rewarming or reperfusion, although the efficacy of intra-arterial thrombolytic therapy suggests that endovascular clotting does occur and can be reversed.^{203–206}

Treatment

Prehospital or field care of the victim of cold injury should focus on removing the patient from the hostile environment and protecting the injured body part from further damage. Rubbing or exercising the affected tissue does not augment blood flow and risks further cold injury or mechanical trauma. Because repeated bouts of freezing and thawing worsen the injury, it is preferable for the patient with frostbite of the hands or feet immediately to seek definitive shelter and care rather than rewarm the tissue in the field and risk refreezing. Although the initial symptoms may be mild and overlooked by the patient, severe pain, burning, edema, and even necrosis and gangrene may appear with rewarming. With severe injury the range of motion progressively decreases and edema becomes prominent. The injury may progress to numbness and, eventually, to loss of all sensation in the affected tissue.

The emergency room treatment of a frostbite victim should first focus on the basic ABCs (airway, breathing, and circulation) of trauma resuscitation and then systemic hypothermia should be identified and corrected. Most patients are dehydrated, and resuscitation with warm fluids is an important part of

early management. Fractures are often accompanied by frostbite in mountaineers, and although manipulation may be required to treat vascular compromise, open reduction is hazardous, and application of traction should be delayed until after postthawing edema has been assessed.

Rapid rewarming is the goal. Gradual, spontaneous rewarming is inadequate, particularly for deeper injuries, and rubbing the injured part in ice or snow often delays warming and results in marked tissue loss.²⁰⁷ Rapid rewarming should be achieved by immersing the tissue in a large water bath of 40°C to 42°C (104°F to 108°F). The water should feel warm, but not hot, to the normal hand. The bath should be large enough to prevent rapid loss of heat, and the water temperature should be maintained. Dry heat is not advocated because it is difficult to regulate, and the result of using excessive heat is often disastrous. The rewarming process should take approximately 30 to 45 minutes for digits, with the affected area appearing flushed when rewarming is complete and good circulation has been reestablished. Narcotics are required because the rewarming process can be quite painful.

The skin should be gently but meticulously cleansed and air-dried and the affected area elevated to minimize edema. A tetanus toxoid booster should be administered as indicated by immunization history. Sterile cotton is placed between toes or fingers to prevent skin maceration and extreme care taken to prevent infection and avoid even the slightest abrasion. The affected tissue should be protected by a tent or cradle, and pressure spots must be prevented. In one review, infection developed in 13% of urban frostbite victims, but one-half of these infections were present at the time of admission.¹⁹⁶ Most clinicians reserve antibiotics for identified infections.²⁰⁸

After rewarming, the treatment goals are to prevent further injury while awaiting the demarcation of irreversible tissue destruction. All patients should be hospitalized and affected tissue gently cleansed once or twice a day in warm (38°C) whirlpool baths, with some clinicians adding an antiseptic such as chlorhexidine or an iodophor to the bath. Based on the findings of arachidonic acid metabolites in the blisters of frostbite victims, some authors advocate the use of topical aloe vera (thromboxane inhibitor) and systemic ibuprofen or aspirin. Heggers et al. report in a nonrandomized trial in which 56 patients treated with these agents, plus prophylactic penicillin, had less tissue loss, a lower amputation rate, and a shorter hospital stay than 98 patients treated with warm saline, silver sulfadiazine, or sulfamylon dressings (Bertek Pharmaceuticals, Research Triangle Park, NC).²⁰⁹ Another report on frostbite treatment in rabbits demonstrated improved tissue viability when systemic pentoxifylline and topical aloe vera cream were used.²¹⁰ Uninfected blebs should be left intact because they provide a sterile biologic dressing for 7 to 10 days and protect underlying epithelialization. After resolution of edema, digits should be exercised during the whirlpool bath and physical therapy begun. Tobacco, nicotine, and other vasoconstrictive agents must be withheld. Weight bearing is prohibited until complete resolution of edema.

Numerous adjuvants have been tried in an effort to restore blood supply to frostbitten areas. The intense vasoconstrictive effect of cold injury has focused attention on increased sympathetic tone. Sympathetic blockade and even surgical sympathectomy continues to be advocated by some authors based on the theory that it releases the vasospasm that precipitates thrombosis in the affected tissue.^{211,212} This method of treatment has produced inconsistent results and is difficult to evaluate clinically, with no prospective, randomized trials available. Although sympathectomy appears to mollify the pain and hyperhidrosis and vasospasm of cold injuries, it may increase vascular shunting and adversely affect healing. In one series, a more proximal demarcation of injury in sympathectomized limbs was noted than in nonsympathectomized ones, despite apparently equal bilateral injury.²⁰⁷

Experience with intra-arterial vasodilatory drugs, such as reserpine, tolazoline, and papaverine, has also been unrewarding. For example, Bouwman et al.²¹² demonstrated in a controlled clinical study that immediate (mean 3 hours) ipsilateral intra-arterial reserpine infusion coupled with early (mean 3 days) ipsilateral operative sympathectomy failed to alter the natural history of acute frostbite injury compared with the contralateral limb. Iloprost, a synthetic analog of prostacyclin PGI₂ has also been used in an effort to vasodilate microvascular arcades.²⁰⁶ Low-molecular-weight dextran has been shown to alleviate postthawing circulatory obstruction as late as 2 hours after thawing and markedly reduced tissue loss in rabbit feet,²¹³ but similar results in humans has not been demonstrated. Heparin, thrombolytic agents, and hyperbaric oxygen have also failed to demonstrate any substantial treatment benefit, but hyperbaric enthusiasts continue to tout its role.²¹⁴ None of these adjuncts is considered routine care.

Figure 33-20. Digital angiography of a 19-year-old woman who sustained bilateral lower extremity frostbite following vehicle breakdown. **A:** The image demonstrates poor distal perfusion to the left toes. **B:** Following administration of tissue plasminogen activator via bilateral femoral catheters, angiography demonstrates return of perfusion. All 10 of her toes were saved. (Reproduced with permission from Bruen KJ, Ballard JR, Morris SE, et al. Reduction of the incidence of amputation in frostbite injury with thrombolytic therapy. *Arch Surg* 2007;142:546–553.)

10 The most recent adjunct to the management of frostbite is the intra-arterial infusion of tissue plasminogen activator (tPA). In a nonrandomized study of a small number ($n = 7$) of patients who received intra-arterial tPA, the burn team at the University of Utah demonstrated that tPA infusion improved tissue perfusion and reduced amputations (10% vs. 41%) when administered within 24 hours of injury (6 of the 7), as compared with 25 patients managed in a more traditional fashion.²⁰³ Since this 2007 report, isolated case reports have also suggested that this therapy is effective.^{205,215} Candidates for this therapy should have minimal risk of bleeding from other injuries, have the tPA administered (intra-arterial or intravenously) within 24 hours of frostbite, with no episodes of rewarming or refreezing between injury and treatment, and have clear evidence of full-thickness tissue involvement, as well as abnormal perfusion on either angiogram or pyrophosphate scanning (Fig. 33-20, Table 33-9).

The difficulty in determining the depth of tissue destruction in cold injury has led to a conservative approach to the care of frostbite injuries.^{208,216} For digit frostbite, the Hennepin score may provide a useful way to track progress and compare experimental therapies.²¹⁷ As a general rule, amputation and surgical débridement are delayed for 2 to 3 months unless infection with sepsis intervenes, hence the adage: “frostbite in January, amputate in June.” The natural history of a full-thickness frostbite injury is the gradual demarcation of the injured area with dry gangrene or mummification clearly delineating nonviable tissue. Often the permanent tissue loss is much less than originally suspected. In an Alaskan series, only 10.5% of patients required amputation, usually involving only phalanges or portions of phalanges.¹⁹³ The need for emergency surgery is unusual, but vigilance should be maintained during the rewarming phase for the development of a compartment syndrome requiring fasciotomy. Open amputations are indicated in patients with persistent infection and sepsis that is refractory to débridement and antibiotics. Mills convincingly demonstrated that of all the factors in the treatment of frostbite that may influence outcome, premature surgical intervention by any means, in any amount, was by far the greatest contributor to poor results.²¹⁸

Table 33-9 Amputation Outcomes of Patients Treated With Tissue Plasminogen Activator (tPA) Compared With All Other Patients by Frostbite

Agent	No. of Patients	No. of Involved Extremities	Extremities Requiring Amputation, No. (%)			No. of Digits Amputated/Total Digits Involved (%)
			None	Proximal	Digits only	
No agent ^a	26	57	25 (45)	14 (25)	18 (29)	97/234 (41)
tPA administration, <24 hrs	6	13	10 (77)	0	3 (23)	6/59 (10) ^b
Total	32	70	35 (50)	14 (20)	21 (30)	103/293 (35)

^aIncludes one patient who received tPA starting 48 hours after exposure.

^b $p < 0.50$ using Mann–Whitney U test.

The use of technetium-99m methylene diphosphonate bone scanning has shown some promise in the early detection of eventual bone and soft tissue viability²¹⁹ as has the use of magnetic resonance imaging.^{220,221} Technetium-99m “triple-phase” scanning (at 1 minute, 2 hours, and 7 hours) performed beginning 48 hours after admission has been used to assess early tissue perfusion and viability, in an attempt to define the extent of fatally damaged tissues and to allow for early débridement and wound closure.^{222,223} The utility of this diagnostic modality continues to evolve, however, with one recent study suggesting that the moderate to severe frostbite lesion identified by technetium-99m scans can be “hibernating” (viable) tissue, which can show improvement up to 6 months following injury.^{208,224}

Frostbitten tissues seldom recover completely. Some degree of cold insensitivity invariably remains. Hyperhidrosis (in up to 72% of patients), neuropathy, decreased nail and hair growth, and a persistent Raynaud phenomenon in the affected part are frequent sequelae to cold injury.^{204,224,225} The affected tissue remains at risk for reinjury and should be carefully protected during any cold exposure. As mentioned previously, chilblain (or chronic pernio) is a specific form of a dermatopathy secondary to cold-induced skin vasculitis. Treatment with antiadrenergic agents (prazosin hydrochloride, 1 to 2 mg/d) or calcium channel blockers (nifedipine, 30 to 60 mg/d) and careful protection from further exposure is often helpful.^{191,224} However, few therapies afford significant relief to the chronic symptoms after tissue freeze injury, although β - and α -adrenergic blocking agents, calcium channel blockers, topical and systemic steroids, and a host of home remedies have been tried with occasional individual success.

SECTION B: TRANSPLANTATION

Chapter 34

Clinical Transplant Immunology

Amit K. Mathur and Satish N. Nadig

Key Points

- 1 Understanding clinical transplant immunology is predicated on understanding mechanisms of innate and adaptive immunity, as well as T- and B-cell signal pathways.
 - 2 T cells are responsible for regulatory and effector mechanisms in the immune response. T-cell effector activity is coordinated by regulatory cells driven by three signals of antigen presentation.
 - 3 Clinical immunosuppression involves induction and maintenance therapies.
 - 4 Induction therapies are used to prevent early acute rejection of allografts, and are generally aimed at reducing T-cell signaling. Commonly used drugs are lymphocyte depletion agents, IL-2 receptor antibodies, agents to block costimulatory signals.
 - 5 Maintenance immunosuppression consists of calcineurin inhibitors, mTOR inhibitors, antimetabolite agents, and steroids. All agents have a clinically significant side effect profile.
 - 6 Acute rejection has a clinical phenotype and may involve cellular infiltration of the allograft as well as antibody-mediated mechanisms. Chronic rejection, or chronic transplant dysfunction, is driven by immune and nonimmune mechanisms and results in progressive graft fibrosis that is heretofore irreversible.
 - 7 Major side effects of chronic immunosuppression include calcineurin inhibitor–related nephrotoxicity, major and minor infections, and cancer.
 - 8 Clinical tolerance is the holy grail of transplantation, and novel targets in regulatory immunocytes have emerged as a promising focus of future research.
-

INTRODUCTION

Modern clinical transplantation has rapidly evolved over the last 50 years. The fortitude of surgeons in the early development of surgical techniques and basic science have enabled thousands of patients to realize the gift of a solid organ transplant. The long-term benefit to adults and children who are on the verge of death from kidney, liver, intestinal, pancreatic, pulmonary, or cardiac failure is directly linked to our cumulative understanding of clinical transplant immunology. The discovery of the immune response to alloantigens and the identification of molecular targets for modern immunosuppressive agents have solidified clinical transplantation as the treatment of choice for patients with organ failure.

Management of the transplant recipient is predicated on understanding the mechanisms and clinical manifestations of the graft immune response, and applying principles of clinical transplant immunology to abate deleterious effects on graft function. Graft injury begins as a result of several complex interactions between inflammatory mediators related to the obligatory ischemia–reperfusion injury tied to surgical recovery, organ preservation, and implantation in the recipient. This inflammatory injury overlaps with graft–host immune interactions, and ultimately promotes graft immunogenicity. This process affects graft function by proliferation of antigen presentation and up-regulation of cell signaling to recruit effector cells that lead to organ injury. These reactions also play a role in the development of chronic rejection of the organ, which may lead to the need for repeat transplant or shortened recipient life expectancy.

The application of transplant immunology principles in the creation of immunosuppression protocols requires an in-depth understanding of the molecular mechanisms that lead to acute and chronic rejection. Transplant rejection is the clinical phenotype of organ injury brought on by the recipient immune system's recognition of allogeneity. The rejection phenotype is the culmination of several signals initiated by antigen presentation and effector mechanisms that operate through humoral- and cell-mediated immune responses. Our growing understanding of transplant immunobiology has been

directly responsible for the development of clinical therapeutics used in immunosuppression induction, as well as maintenance therapy to prevent rejection, and in salvage situations to treat rejection once it has occurred.

The aim of this chapter is to review the scientific principles behind the use of modern immunosuppressive agents, the interplay between cell types involved in the alloimmune response, and an in-depth discussion of modern therapeutics applied to the clinical management of the transplant patient. Additionally, the complications of immunosuppressive therapy and evolving therapies will be discussed.

SCIENTIFIC BASIS OF MODERN CLINICAL IMMUNOSUPPRESSION

The Immune Response to a Solid Organ Transplant

1 The interaction of a host's immune system with foreign antigen is central to understanding the pathways that modulate organ-directed effector responses. *Operational tolerance* is defined as the immunologic acceptance of an organ allograft while maintaining global immune system integrity; down-regulation of host effector mechanisms must be maintained while minimizing the suppression of recipient defence mechanisms. T- and B-cell activation and regulatory pathways are primary targets for conventional immunosuppressive regimens. Immunosuppressive regimens have been developed to impact isolated pathways in T-cell activation by recipient antigen-presenting cells (APCs). As the field of transplantation has matured, these pharmacotherapies have become more specific and less toxic to the host immune system.

The development of mature T cells begins with nascent thymocytes. Thymocytes contain T-cell receptors (TCR) arranged and rearranged in a random individual-specific manner. These TCR-containing thymocytes are challenged by “self” antigen and undergo programmed cell death if they express “high affinity” and activate. In contrast, these immature cells are programmed not to proliferate if they express “too low” an affinity. Thymocytes with an intermediate affinity are fostered to survive and differentiate into specific CD4- and CD8-expressing cells which interact with self-restricted major histocompatibility complexes (MHCs) on APCs, such as dendritic cells, in the peripheral blood.

The foundation of the adaptive immune response lies in the presentation of antigen to T cells which takes place via macrophages, B cells, and dendritic cells. Dendritic cells present antigen via their MHC class I or II molecules to CD8⁺ T cells and CD4⁺ T cells respectively. The most common scenario occurs when a T cell interacts with an APC–MHC complex presenting “self” antigen. In normal (nonautoimmune) circumstances, this is usually a very weak bond and the T cell removes itself from the interaction and begins to recirculate. In the context of infection or transplantation, the APC–MHC complex presents a foreign peptide which the T cells recognize as “nonself” and begin the cascade of activation as well as clonal expansion.

2 T cells are activated by a process that requires three sequential signals. The “three signal” process of T-cell activation begins with signal 1 as the TCR interacts with the MHC–foreign peptide complex presented by an APC. T cells become maximally activated only after a threshold number of TCRs have been occupied.¹ Once this occurs, multiple costimulatory supporting molecules on the periphery of both the APC and T cells “ride” lipid rafts to the synapse of the TCR–MHC interaction.^{2,3} Once these costimulation molecules have reached the immunologic synapse they begin to interact with each other, comprising signal 2. The engagement of TCR by MHC–peptide complexes in combination with the interaction of costimulatory, accessory, and adhesion molecules results in a cascade of signaling pathways including activation of NFκB and translocation of the nuclear factor of activation and transcription (NFAT) to the nucleus of the T cell which translates and transcribes proteins such as interleukin-2 (IL-2).⁴ IL-2, formerly known as T-cell growth factor, then contributes to the clonal expansion of other T-cell populations allowing for cellular expansion to fight against the inciting foreign antigen. IL-2 also engages with CD25 on the T cell itself thereby activating a doublet complex known as the mammalian target of rapamycin, or mTOR. Signaling through mTOR constitutes “signal 3” of activation which affects cell cycling and cytokine production, cellular proliferation, and T-cell differentiation into an effector cell against the grafted organ. This pathway initiates the slower, more sophisticated, adaptive immune response (Fig. 34-1).⁵

Immediately following implantation and reperfusion of an organ allograft, markers of inflammation are up-regulated which act as homing signals to effector T cells. These inflammatory mediators also allow for a more efficient uptake of antigen by dendritic cells. Organ-derived dendritic cells are released

to the host's secondary lymphoid tissue. Termed "passenger leukocytes," these dendritic cells are primed to present antigen to naïve host T cells.^{6,7} These activated CD4⁺ T cells specialize into subsets of helper T cells each identified by a distinct signature of cytokines. Interferon- γ (IFN γ) secreting T_H1 cells are central to various cell-mediated rejection responses including acute and chronic or delayed-type hypersensitivity responses. T_H2 cells support B-cell production of antibody and secrete cytokines with a suppressive capacity such as IL-4 and IL-10.⁷ T_H17 cells secrete IL-17, which is a potent instigator of tissue injury in the setting of transplantation and autoimmune diseases.⁸

Figure 34-1. The signal hypothesis of T-cell activation and molecular targets of modern clinical immunosuppression. T-cell activation requires three signals to initiate an effector response: antigen presentation of nonself MHC, costimulatory signal, and regulation of cytokine signaling at the cell surface. These three signals are thus targets for therapeutic drugs used in modern clinical immunosuppression in both induction and maintenance phases, as well as in the treatment of rejection. The figure demonstrates the site of action of these agents.

Memory T-cell subsets react in a more rapid manner to the graft and incite an accelerated rejection response. Seminal studies investigating memory responses to allografts proved that antigen-experienced memory T-cell subsets can cause graft destruction in the absence of secondary lymphoid tissue.⁹ Clinically, these "memory" T cells are generated throughout the lifespan of a potential recipient due to various infections that the patient may have experienced. Memory T-cell subsets that have been generated by these infections may then react against an organ at the time of transplant if the antigenic response from the organ mimics that of the previous infectious episodes. This concept of "heterologous immunity" may account for early rejection responses in patients who have not been classically sensitized by foreign human antigen by transfusion, pregnancy, or previous transplant.¹⁰ Studies have also suggested that certain induction therapies may eradicate naïve host T cells yet spare memory subsets which may also contribute to potential early rejection responses and express resistance to tolerance induction.¹¹⁻¹³

Immunosuppression Induction in Solid Organ Transplantation

Human immunity depends on innate and adaptive responses to foreign antigen. The innate response is rapid and nonspecific when foreign antigen is encountered; the adaptive response develops over time and harbors the ability to recall pathogens upon each successive insult. Therefore, adaptive immunity becomes more efficient with each antigenic interaction. The innate immune response usually sets the scene for the adaptive response but it is the antigen specificity of the adaptive response that allows for activation and proliferation of effector cells to rid the system of the pathogenic insult. Current therapies in clinical immunosuppression target this global activation and proliferation of T cells.

3 Induction immunosuppression is used intraoperatively and/or perioperatively as a prophylactic treatment to attenuate acute rejection responses in the first few months after transplant when the risk is highest.¹⁴ Various induction strategies have been developed in order to spare the use of toxic calcineurin inhibitors (CNIs) and steroids.

CELL SURFACE RECEPTOR BLOCKADE

4 Each of the three signals in T-cell activation is uniquely important and each depends on the other for cellular proliferation and effector cell differentiation (Fig. 34-1).^{15,16} If one signal acts in isolation without the others, anergic or apoptotic signal ensues.^{17,18} With this knowledge, various pharmacotherapies have been developed to block signal 2, or costimulation, in order to inhibit the clonal proliferation of the effector T cell. Several pathways are involved in the make-up of the second signal in lymphocyte activation. Costimulation pathways have been targeted by various types of biologics including monoclonal antibodies as well as recombinant fusion proteins.

A specific APC-T-cell interaction is crucial. The engagement of APC-derived CD80/86 (B7 molecules) with CD28 on T cells (members of the Ig superfamily) is integral to positive costimulation.⁵ Pharmacotherapies targeting other costimulatory pathways are in various phases of development and include monoclonal antibodies to CD40 as well as CD2. Although costimulation blockade has been successfully utilized for the induction of tolerance in rodent models, this has not been realized in humans. Costimulation blockade has proven to be beneficial when used as maintenance immunosuppression.¹⁹

The initiation of signal 3 begins with the engagement of IL-2 on CD25 located on the surface of the T cell. IL-2 receptor blockade has become standard of therapy in the perioperative period (day 0 and day 4) to allow for early allograft acceptance and reduced usage of nephrotoxic CNIs. Early clinical trials proved that induction therapy with IL-2 receptor blockade significantly reduced acute rejection rates in renal transplant recipients when compared to placebo groups and in combination with standard CNIs and steroids.²⁰

B7/CD28 CTLA4 Blockade

The expression of CD80 (B7.1) and CD86 (B7.2) on the surface of APCs provides T cells with either activation signals, if engaged to CD28, or inhibitory signals, if ligating cytotoxic T-lymphocyte antigen 4 (CTLA4). CD80 and CD86 interact preferentially with CTLA4 (CD152) when compared to CD28.^{18,21} CTLA4 is also up-regulated following the activation process and its ligation results in inhibition of activation thereby controlling clonal expansion.^{22,23} Additionally, CTLA4 is constitutively expressed on regulatory T cells.²⁴ Blockade of each B7 molecule as monotherapy has not led to significant allograft survival in nonhuman primate models. In contrast, blockade of both B7 molecules together did lead to prolonged graft survival but was not able to induce tolerance as rejection occurred once therapy was stopped.^{25–27} An immunoglobulin fusion protein of CTLA4 (abatacept), has been shown to inhibit graft rejection in xenogeneic and allogeneic systems.^{28,29} These promising early results have prompted the development of CTLA4-Ig variants.

LEA29Y (belatacept) is a second-generation molecule, derived as a result of mutating two amino acids of CTLA4-Ig. Belatacept possesses a twofold greater ligation capacity for both CD80 and CD86. The increase in avidity allows for a more complete blockade of the B7 molecules and a 10-fold greater suppression in in vitro assays.³⁰ Belatacept has shown improved renal function, reduction in chronic allograft nephropathy, decreased calcineurin-related toxicity, and no thromboembolic complications in phase II trials.³¹ Phase III trials have evaluated the efficacy and renal protection of belatacept in standard (BENEFIT) and expanded criteria donors (BENEFIT-Ext). There was an increased incidence of posttransplant lymphoproliferative disease in Epstein–Barr virus (EBV)-seronegative patients and acute rejection at 1 year in the belatacept treatment groups compared to CNIs. Additional results revealed an improved glomerular filtration rate (GFR) and lipid profile over a 5-year period.^{32–35}

IL-2 Receptor Blockade

Basiliximab is a chimeric mouse/human IgG1 monoclonal antibody to the alpha chain of CD25 (IL-2 receptor) which has proven to reduce acute rejection rates in adult and pediatric renal and pancreas transplant recipients. In clinical trials with 6-month follow-up, basiliximab had a significant impact on acute rejection rates with no increase in infectious complications.³⁶ Often used in kidney transplant

patients as induction therapy, and in liver transplantation in order to spare the nephrotoxic effects of tacrolimus, long-term follow-up remains to be provided.^{37–39} In a randomized, prospective, placebo-controlled trial of patients investigating immunoprophylaxis in liver transplantation, investigators identified a lower acute rejection rate in HCV-negative patients at 6-month follow-up in patients treated with basiliximab in combination with standard CNi therapy.⁴⁰

LEUKOCYTE DEPLETION

In order to achieve tolerance to an organ transplant, it may be necessary to maximize the potential of engraftment by depleting the alloreactive effector T cells (and B cells in some therapeutic regimens) which mediate a rejection response. Many investigators have identified the value of monoclonal or polyclonal antibodies designed to bind to peripheral alloreactive lymphocytes. The short-term depletion of leukocytes using antithymocyte globulin, anti-CD3, anti-CD2, anti-CD4, and anti-CD8 has proven successful in terms of long-term graft survival in animal models; these results are further enhanced with thymectomy prior to transplantation in order to prevent posttransplantation peripheral effector cell repopulation.^{41,42} In nonhuman primate models, anti-CD3 conjugated to diphtheria immunotoxin administered alone prior to transplantation or in conjunction with sirolimus (rapamycin) or deoxyspergualin, inhibitor monocytes and macrophages, produced tolerance via T-cell depletion.^{43–45} Clinical trials in kidney transplant recipients using anti-CD52 antibody (alemtuzumab)–mediated leukocyte depletion alone and in combination with deoxyspergualin were not able to induce tolerance.^{46,47} In subsequent trials, alemtuzumab therapy allowed for the use of low-dose immunosuppression in steroid-free regimens in order to control effector responses; alemtuzumab is now a commonly used and inexpensive induction agent.^{48–52} Memory T cells are the most resistant to depletion with alemtuzumab therapy.^{13,53}

Polyclonal leukocyte-depleting antibodies, such as thymoglobulin (rabbit antithymocyte globulin [rATG]), are useful as induction agents, and are mainstays of induction therapy in renal transplant recipients.⁵⁴ Upon binding various T-cell epitopes, rATG lyses leukocytes using complement-dependent pathways and opsonization leading to mononuclear cell phagocytosis of T cells.⁵⁵ rATG also binds to surface receptors on dendritic cells, which impair antigen presentation.⁵⁵ Polyclonal antithymocyte globulin is wrought with serious side effects including a predisposition to posttransplant lymphoproliferative disorder and the cytokine release syndrome.^{56,57}

Depleting the recipient of leukocytes creates a window of opportunity for an allograft to “settle in” without attack by effector immunocytes. The recipient’s transient immunodeficiency is dictated by the strength and duration of depletion. T-cell depletion strategies have paved the way for future studies involving administration of donor antigen along with leukocyte depletion in an attempt to achieve chimeric states.⁵⁸

CLINICAL THERAPEUTICS FOR MAINTENANCE IMMUNOSUPPRESSION IN SOLID ORGAN TRANSPLANTATION

Calcineurin Inhibitors

5 One of the greatest medical discoveries of 20th century was the identification of the CNIs with their effects on T-cell signaling, and their alterations in cell-mediated immunity. This class of agents has potent biologic activity and minimal myelosuppressive effects, which were a significant limitation in early clinical transplantation. Cyclosporine A was the first of these drugs identified, initially found in a soil sample from the fungus *Tolypocladium inflatum*. Cyclosporine is a cyclical fungal peptide composed of 11 amino acids, with significant immunosuppressive effects.^{59,60} Subsequently, the clinical efficacy of cyclosporine A was demonstrated in human kidney transplantation, opening the gates to a new era for clinical organ transplantation. Cyclosporine remained the mainstay of clinical immunosuppression for several years, and was used across organ types by thousands of patients. In 1984, FK506 (tacrolimus) was identified as another CNI with a similar mechanism of action. FK506 is a macrolide immunosuppressant that was approved by the U.S. Food and Drug Administration for use in liver transplantation.^{61–63} Tacrolimus has become the mainstay of maintenance immunosuppression in solid organ transplant programs due to a gentler side effect profile and potency of immunosuppression, and is used in virtually all solid organ types.

CNIs, as a class, disrupt regulatory T-cell signaling and lead to a down-regulation of IL-2 production, which eventually decreases the activity of cytotoxic T cells. Antigen presentation at the TCR leads to an increase in cytoplasmic calcium levels through a protein kinase and G-protein reaction within regulatory T cells. This calcium binds to calmodulin, a regulatory subunit of the phosphatase calcineurin, prevalent in immunocompetent lymphocytes and nerve cells. Calcineurin is responsible for cleaving the phosphate bound to NFAT (nuclear factor of activated T-cells) which in its activated form traverses the T-cell nuclear membrane and promotes transcription of IL-2. Inhibition of calcineurin occurs through the activation of immunophilins, such as cyclophilin and FK-binding protein, which are endogenous cytosolic peptides. The cyclosporine–cyclophilin complex and its counterpart, the FK506–FKBP12 complex, prevent dephosphorylation of NFAT, which in turn leads to reduced IL-2 production and diminished T-cell signal transduction to effector lymphocytes.

Side Effects

CNIs have a variety of side effects which present challenges in the clinical management of transplant recipients. One of the issues relates to drug interactions for patients on tacrolimus or cyclosporine. Common interactions that may boost levels of CNIs occur in patients requiring antifungal therapy, particularly in the azole class, as well as other drugs metabolized by hepatic/intestinal cytochrome P450 3A4 enzyme. As implied by the name, calcineurin is also present in nerve tissue as well as lymphocytes. Drug activity in nerve tissue leads to several clinical effects including tremors, seizures, and posterior reversible encephalopathy syndrome.⁶⁴ Additional side effects include hyperkalemia, hypercholesterolemia, and gastrointestinal dysfunction including diarrhea. Cyclosporine has also been associated with gingival hyperplasia that is seen less frequently with tacrolimus. The most significant long-term effects include chronic nephrotoxicity that may precipitate end-stage renal disease, as well as new-onset diabetes mellitus after transplantation. Consultation with a transplant pharmacist is integral to the successful management of the posttransplant patient to prevent toxicity and achieve therapeutic immunosuppression goals.

mTOR Inhibitors

The first discovered mTOR inhibitor was sirolimus. Sirolimus, or rapamycin, is a bacterial macrolide derived from *Streptomyces hygroscopicus*, found initially in a soil sample from Easter Island (Rapa Nui). Like CNIs, its mechanism of action leads to decreased IL-2 proliferation. Sirolimus binds to FK-binding protein 12, as does tacrolimus. The site of action of the sirolimus–FKBP12 complex is known as the mammalian target of rapamycin, or mTOR. Despite having structural similarity to tacrolimus, sirolimus has limited activity on calcineurin when bound to FKBP12. The complex disrupts signal transduction of the IL-2 receptor and decreases nuclear transcription of molecules active in lymphocyte homing.⁶⁵ Sirolimus also has significant antiproliferative properties, and inhibits cell cycle activity in lymphocytes and fibroblasts.^{66–68}

Sirolimus has been adopted in a variety of clinical protocols. Sirolimus is currently used primarily in place of CNIs, most commonly in patients who are weeks to months out from the transplant operation.⁶⁹ Sirolimus has less nephrotoxicity than CNIs, but has been associated with a higher risk of acute rejection in some studies. In liver transplantation, conversion from tacrolimus to sirolimus in patients with reduced kidney function was associated with more acute rejection episodes but did not have a tangible benefit in terms of kidney function in a randomized control trial.⁷⁰ Some have advocated for lower-dose CNIs as maintenance therapy in patients with impaired renal function compared to sirolimus monotherapy,⁷¹ and studies have demonstrated the potential of low-dose CNIs in conjunction with sirolimus for maintenance immunosuppression. Importantly, there is an FDA black box warning against using sirolimus in conjunction with higher-dose CNIs due to higher risk of mortality and graft loss in liver transplantation, as well as an increased risk of hepatic artery thrombosis within the first month after transplant.

Everolimus is another mTOR inhibitor that has recently been approved for use in kidney and liver transplantation. Everolimus is a hydroxylated derivative of sirolimus, and its preserved structure allows for a similar mechanism of action via FKBP12 binding and mTORC1 inhibition. Its immediate appeal was its lower risk of nephrotoxicity. In a recent multicenter prospective clinical trial, patients with reduced-dose tacrolimus and everolimus had improved GFR at 2 years posttransplant compared to patients on standard tacrolimus-based regimens, without any higher risk of biopsy-proved acute rejection or major side effects.^{72,73} This improvement in GFR has also been identified retrospectively in patients converted to everolimus in maintenance immunosuppression.⁷⁴

Side Effects of mTOR Inhibitors

Sirolimus has been associated with impaired wound healing after transplant, including anastomotic dehiscence in lung transplantation, surgical site infections, and fascial union problems.^{75–80} Surgeons confronted with transplant patients who are on mTOR inhibitors should consult with transplant professionals prior to operative intervention if possible, in order to guide alterations in immunosuppressive therapy to minimize complications. Several other complications have been noted in patients on mTOR inhibitors. Pulmonary toxicity manifested as pneumonitis has been identified, and caution should be taken in administering the drug to patients with pre-existing lung disease. Metabolic complications including hyperlipidemia and new-onset diabetes mellitus after transplant have also been identified as significant side effects.⁸¹ In low- to moderate-risk renal transplant recipients, conversion from tacrolimus to mTOR inhibitors was associated with a higher risk of acute rejection, higher rates of proteinuria, hypercholesterolemia, and anemia.⁸¹

Antimetabolite Drugs

Antimetabolite drugs in solid organ transplantation comprise a class of agents aimed at suppressing lymphocyte proliferation by reducing the rate of de novo purine synthesis, which prevents effective nucleotide synthesis and DNA transcription. Typically, these drugs are used in combination with CNIs and steroids. One of the first antimetabolite drugs applied in clinical transplantation was azathioprine. Azathioprine has been applied in a multitude of disease states including inflammatory bowel disease and autoimmune diseases such as rheumatoid arthritis and systemic lupus erythematosus. While it is effective in reducing T-cell and B-cell propagation, azathioprine is also a potent suppressive agent of bone marrow, increases the risk of anemia, and is also associated with pancreatitis.

A newer antimetabolite, mycophenolic acid (MPA), has emerged as a mainstay in solid organ transplantation. MPA was identified in a *Penicillium* fungal species, and is hepatically metabolized. MPA has less myelosuppressive activity than azathioprine, but side effects are common.

Side Effects of Antimetabolite Drugs

Myelosuppression and leukopenia are common side effects of this class of agents. Mycophenolate is also associated with a significant risk of gastrointestinal dysfunction including diarrhea, nausea, and vomiting. Azathioprine has been recognized as a group 1 carcinogen by the National Toxicology Program in the United States, related to length of use and dosage.^{82–85} Mycophenolate should be avoided in pregnancy or in transplant recipients trying to conceive due to the risk of miscarriage and congenital malformations.^{86–90}

Steroids

Steroids have represented the mainstay of immunosuppressive therapy since the beginning of clinical transplantation. Glucocorticoids are steroids that arise from the zona fasciculata in the adrenal gland. These molecules have a plethora of effects in humans, and their receptors are omnipresent across human cell types. In lymphocytes, glucocorticoids act on cytosolic receptors that in turn lead to a variety of intracellular signals that are responsible for gene transcription, and decrease the expression of several cytokines, including IL-2. Glucocorticoids also reduce the number and function of both T cells and B cells.

Side Effects of Steroid Therapy

Steroid therapy is used in a variety of clinical treatments including maintenance immunosuppression and in high doses as a rescue therapy in patients presenting with acute rejection. There are several side effects to chronic corticosteroid use, which have prompted transplant clinicians and researchers to develop protocols that reduce the need for chronic steroid use. Common side effects include glucose intolerance, weight gain, skin and tissue frailty, osteopenia and osteoporosis, muscle breakdown, neuropsychiatric dysfunction, glaucoma and cataracts, secondary hypercortisolemia, and other effects. Many transplant programs are shifting toward steroid avoidance in maintenance immunosuppression in low-risk patients.^{91–93}

TREATING REJECTION IN SOLID ORGAN TRANSPLANTATION

6 Immunologic rejection can occur minutes to years after an organ transplant. The early phases of

rejection, termed hyperacute rejection, can occur on the operating room table to 24 hours after surgery and is mediated by the humoral immune system. Acute rejection is a cell-mediated phenomenon which often manifests days to months after transplant. Chronic rejection occurs in the months to years after transplant and continues to be one of the leading causes of graft loss in the long term. Acute and chronic antibody-mediated rejection (AMR) is a separate phenomenon that may occur days to years after transplant and remains an important barrier to successful engraftment of organs.

Hyperacute Rejection

Hyperacute rejection is a rare clinical entity in modern clinical transplantation. Hyperacute rejection is generally attributed to ABO blood group incompatibility or the presence of preformed anti-HLA antibodies. In the allograft, the capillary endothelium expresses blood group antigens which may join with circulating antibodies to A and B glycoproteins. For example, a blood group B transplant candidate would have circulating anti-A IgG antibodies in blood. If a blood group A kidney allograft were transplanted into that recipient without any other treatment, these antibodies would react with the donor endothelium and activate complement and humoral immunity effector mechanisms, which would lead to endothelial injury, thrombosis, as well as intraparenchymal hemorrhage. This response usually happens within minutes after reperfusion of the allograft, and requires removal of the allograft in order to prevent a systemic inflammatory response which may lead to multiorgan failure. Prevention of this type of rejection is central to the practice of clinical transplantation, and mandates confirmation of donor and recipient compatibility via ABO blood group verification and cross-matching prior to implantation of the allograft.

Acute Rejection

Induction protocols in combination with immunosuppressive therapy successfully prevent the relatively quick onset of acute rejection episodes. In the case of renal transplantation, induction therapies in combination with potent maintenance therapies have fostered a significant improvement of 1-year outcomes.⁹⁴ Less than 10% of organs experience clinically significant acute cellular rejection (ACR) episodes leading to graft loss at 1 year.⁹⁵ As discussed above, ACR is an adaptive response characterized by T-cell interactions with donor antigens either presented directly by the donor APC or indirectly by the recipient professional presenting cells.⁹⁶ Once clonal expansion occurs “effector” T cells then infiltrate the graft and mediate various methods of organ injury.

The gold standard in pathologic categorization of renal transplant rejection is the Banff classification model. The Banff classification originated at a consensus conference in 1991 aimed at ranking the levels of rejection seen on kidney transplant biopsies based on degree of structural damage, such as tubulitis, arteritis, and cellular infiltrate.⁹⁷ In renal transplantation, the diagnosis of ACR occurs with tissue confirmation after ruling out other causes for declining graft function. Treatment of ACR is usually dictated by the Banff classification. For example, borderline rejection characterized by Banff class IA or IB is often treated with pulse corticosteroids and increases in maintenance immunosuppression whereas, more severe ACR is more often treated with multiple doses of thymoglobulin. Today, ACR is often the result of inadequate immunosuppression due to noncompliance/adherence or early immunosuppression withdrawal/underdosing. Repeated episodes of acute rejection are associated with chronic dysfunction and early graft failure.

Chronic Rejection

The clinical sequelae of chronic rejection (more recently termed chronic transplant dysfunction or CTD) are varied and organ specific. The unifying factor of CTD among all organs transplanted is the histopathologic effect of arterial intimal thickening in the vessels supplying the organ, termed transplant arteriosclerosis or transplant vasculopathy. Both immune and nonimmune stimuli may up-regulate pathways leading to progressive graft fibrosis. Immune-dependent mechanisms, including HLA mismatching, inadequate immunosuppression, and episodes of acute rejection, promote the development of CTD and eventual graft failure. Additionally, immune-independent mechanisms, such as prolonged ischemia time and usage of brain dead donor organs, as well as recipient factors such as native hypertension may also play a role in the onset of CTD. Various studies suggest that the development of vascular fibrosis progressing to parenchymal fibrosis is multifactorial and includes effector responses mediated by complement, CD4⁺ T cells, CD8⁺ T cells, and alloreactive antibodies.^{98–102}

Type of Rejection	Time of Onset	Mechanism	Morphology
Hyperacute	Minutes to few hours	Preformed antibodies bind to graft endothelium	Vessel thrombosis; Ischemic necrosis
Acute Cellular	Days to weeks, months to years	T cells injure graft by direct cytotoxicity and type IV hypersensitivity	Interstitial infiltrates of lymphocytes; Focal necrosis of graft tissue
Acute Humoral (Rejection Vasculitis)	Days to weeks, months to years	Antidonor antibodies against graft antigens	Vasculitis; Intimal thickening; Thrombosis
Chronic	Months to years (Irreversible)	T cell cytokines stimulate vascular smooth muscle proliferation	Arteriosclerosis; Ischemic atrophy; Interstitial fibrosis

Figure 34-2. Time course, mechanism, and morphology of transplant rejection. Allograft rejection responses have many different phenotypes, which also lead to different therapies. This figure provides a summary of the types of clinically significant rejection episodes, the root cause behind them, and histopathologic features identified on biopsy.

Clinically, the manifestations of CTD depend on the type of organ allograft. Recipients of renal allografts with CTD often manifest with proteinuria, decreases in GFR, increases in plasma creatinine, and arterial hypertension. Patients who have undergone liver transplantation may present with abnormal liver function tests or an increase in serum bilirubin secondary to the so-called *vanishing bile duct syndrome*. Bronchiolitis obliterans, detected by computed tomography and altered pulmonary function tests indicate the onset of CTD in lung transplant recipients. Patients receiving cardiac allografts may present with a range of symptoms from arrhythmias to fatal myocardial infarction.¹⁰³

The timing, mechanism, and morphology of hyperacute, acute, and chronic rejections are summarized in Figure 34-2.

Antibody-Mediated Rejection

Antibody-mediated rejection or AMR can occur in both the acute and chronic phases of transplantation. Increasingly, AMR has been shown to occur in multiple organs including liver and heart.¹⁰⁴ AMR starts with production of donor-specific antibody (DSA) directed to the endothelial lining of organ allografts. DSA–endothelial cell interactions lead to complement activation as well as innate responses resulting in allograft injury.^{105,106} In the chronic setting, persistent DSA leads to microthrombotic events and late graft failure. Diagnostically, along with serum titers of circulating DSA, tissue biopsy reveals deposition of complement split products including C4d and inflammation of capillaries and renal tubules. AMR has also been diagnosed using newer endothelial, cell-specific biomarkers of capillaritis.¹⁰⁷ Liver allografts have shown susceptibility to AMR and DSA in recent studies.¹⁰⁸

The treatment of acute AMR is based on removal of inciting antibodies (Fig. 34-3). Although there are no high-quality evidence-based treatments for acute AMR, strategies include plasmapheresis, immunoadsorption, use of B-cell toxic antibodies such as rituximab, newer proteasome inhibitors such as bortezomib, and even splenectomy.¹⁰⁹ In patients with drug-resistant AMR, monoclonal antibodies to complement C5 (eculizumab) have been used off-label with some encouraging results although the extreme expense of the drug has hindered its investigation in randomized control trials.¹⁰⁹

Figure 34-3. Current strategies to treat various phases of antibody-mediated rejection. Antibody-mediated rejection involves antigen presentation, T-cell signaling, and effector responses that result in stimulation of B cells, antibody formation and release, and antibody deposition and initiation of the innate immune response via complement activation. This figure demonstrates the site of action of drugs and treatments common to antibody-mediated rejection treatment protocols, which are ultimately aimed at reducing antibody. (Adapted from Djamali, Kaufman DB, Ellis TM, et al. Diagnosis and management of antibody-mediated rejection: current status and novel approaches. *Am J Transplant* 2014; 14:25514;plantand management.)

COMPLICATIONS OF IMMUNOSUPPRESSIVE THERAPY

7 The need for continued immunosuppression after transplant is a necessary evil in clinical transplantation. In order to maintain long-term graft function, the immune system is suppressed as discussed using a variety of agents. Long-term exposure to these agents does carry a risk of serious complications that must be discussed with any patient considering a transplant for the treatment of end organ failure.

Renal Failure with Calcineurin Inhibitors

The nephrotoxic effects of CNIs have long been recognized in clinical transplantation, and several protocols have been designed to reduce the risk of acute and chronic renal failure in the renal and nonrenal solid organ transplantation. Registry analyses suggest that 7% to 21% of nonrenal transplant recipients are at risk for renal failure, and patients treated with CNIs are at significantly increased risk of requiring dialysis treatment in the months and years after transplant.¹¹⁰

In the acute setting immediately after transplant, CNIs may cause renal dysfunction by affecting renal blood flow via several mechanisms including vasoactive/nitric oxide-dependent pathways, as well as activation of the renin/angiotensin system. These mechanisms result in increased renal vascular resistance and lower GFR. In the early posttransplant setting, these nephrotoxic effects are typically reversed with reduction in CNI dosage, and seem to be independent of plasma concentration.

CNI-related renal dysfunction may also result in chronic organ injury. Histologically, kidneys demonstrate interstitial fibrosis and tubular atrophy. Cyclosporine has been implicated in up-regulation of TGF-beta, a profibrotic cytokine.¹¹¹ Reduction in CNI dosage does not improve renal function in the long term in patients with global fibrosis, and patients may require renal replacement therapy. In liver transplantation, the need for long-term dialysis represents a significant increase in posttransplant mortality risk and attenuates the survival benefit of the initial transplant.^{112–115} In order to preempt CNI-associated effects on kidney function, patients with pre-existing renal insufficiency and other end organ failure are often considered for combined nonrenal and renal transplantation if they meet certain criteria.

Infections after Transplant

Posttransplant infections are directly related to the level of immunosuppression in the host. In the early period after transplant, when levels of immunosuppression are high and proximal to the use of T-cell depleting induction agents, the risk of opportunistic infections is high and management is focused on antimicrobial prophylaxis. Further from transplant, less immunosuppression is typically required, and prophylaxis is not necessary. However, the prevalence and incidence of infectious diseases in solid organ transplant recipients mandate close monitoring of clinical signs and symptoms, and appropriate diagnostic testing when a clinical suspicion arises of a bacterial, viral, parasitic, or fungal infection. Infections after transplant may consist of donor-derived infections transmitted with the organ, recipient-derived infections due to colonization or other pretransplant exposure, nosocomial infections acquired in the healthcare setting, and community-acquired infections.¹¹⁶ Figure 34-4 demonstrates the peak incidence of common opportunistic infections as a function of time after transplant. When faced with a transplant patient with a high clinical suspicion of an infection, transplant providers and infectious disease specialists use this information, clinical history, affected organs and systems, and a battery of cause-oriented diagnostic tests to establish the diagnosis and treatment strategy (Fig. 34-5).

Donor-Derived Infections

Deceased organ donors may be exposed to community-acquired infections prior to death, infectious risk related to lifestyle exposures (i.e., intravenous drug abuse), as well as nosocomial infections acquired during hospital care. Several infectious transmissions have occurred as a result of donor transmission,

including human immunodeficiency virus (HIV), West-Nile virus, rabies, Chagas disease, and lymphocytic choriomeningitis virus. Careful attention must be paid to the circumstances surrounding the donor’s death as well as reported signs and symptoms such as fever and altered mental status. Prior to organ recovery, organ donors are routinely serologically screened for several infectious pathogens, including HIV, hepatitis, cytomegalovirus (CMV), EBV, and syphilis. Routine blood, urine, and sputum cultures may be used in premortem care. Serologic testing consists of antibody testing, which is not 100% sensitive, but the recent inclusion of nucleic acid testing in many centers may help mitigate risk in organ acceptance and aid patient counseling.¹¹⁷ In the case of CMV, hepatitis, and EBV serologic testing, serologic matching between donors and recipients drives the perception of posttransplant infectious risk and guides antimicrobial prophylaxis decisions and selection of immunosuppression.

Figure 34-4. Timeline of common infections after transplantation. Immunosuppression predisposes transplant recipients to infection by deterring host defenses. In this context, bacterial, viral, and fungal infections may arise which have distinct peaks of onset. Treatment of these infections usually involves withdrawal or reduction of immunosuppression in most cases, particularly when infections are life-threatening or are causing significant morbidity. (Adapted from Fishman JA. Infection in solid-organ transplant recipients. *N Eng J Med* 2007;357:2601–2614.)

Recipient-Derived Infections

The incidence of posttransplant infections that arises from pretransplant exposure to the recipient is increasingly recognized. Transplanting patients with active infections should be undertaken with extreme caution due to the risk of dissemination of disease with early immunosuppression.

Nosocomial pathogens may colonize the recipient prior to transplant, when healthcare utilization may be high due to organ failure, or may infect patients at any point after transplant. Pathogens may acquire antibiotic resistance which may make treatment difficult, such as in cases with vancomycin-resistant *Enterococcus*, methicillin-resistant *Staphylococcus*, azole-resistant *Candida*, as well as in *Clostridium difficile colitis*, several gram-negative enteric pathogens, and fungi.¹¹⁶ Recipient exposure via travel or residence in geographically endemic areas can also be a risk for infection (fungal infections such as histoplasmosis, aspergillosis, coccidiomycosis, atypical bacterial infections such as *Mycobacterium tuberculosis*, parasitic infections caused by *Strongyloides* or *Trypanosoma cruzi*), as well as reactivation of dormant viruses (hepatitis, CMV, or varicella-zoster virus). Exposures to relatively benign pathogens may result in major infections after transplant. Respiratory viruses may further weaken natural tissue defenses in the bronchopulmonary tree and lead to superinfection with other pathogens. Fungal infections derived from the soil such as *Nocardia* or *Aspergillus* may arise in this fashion, and require changes in immunosuppression to prevent exacerbation of infection.

Pathogen	Site of Disease	Disease Manifestations	Prophylaxis	Treatment
Cytomegalovirus (CMV)	CNS, Respiratory, GI tract, Bone marrow	Fever, neutropenia, pneumonitis, diarrhea, mucosal ulceration, chorioretinitis, meningoencephalitis, graft dysfunction	Low risk patients: Acyclovir High Risk patients: Valganciclovir	Valganciclovir Ganciclovir CMV-immunoglobulin Minimization of immunosuppression
Epstein-Barr Virus (EBV)	Bone marrow, spleen, CNS	B-cell-derived post transplant lymphoproliferative disease (PTLD)	Antiviral prophylaxis such as acyclovir or valganciclovir	Minimization of immunosuppression Chemotherapy Radiation Therapy (CNS) Anti-CD20 antibody therapies
BK Virus	Kidney	Renal Dysfunction	None	Minimization of immunosuppression Experimental antiviral therapies (cidofovir)
Pneumocystis	Respiratory	Pneumonia/pneumonitis	Trimethoprim/sulfamethoxazole Pentamidine Dapsone	

Figure 34-5. Common infections after transplantation, prophylaxis, and treatment strategies. After transplant, while predisposed to multiple infections related to immunosuppression, certain infections are particularly common and virulent. Clinical decisions regarding prophylaxis against these pathogens and how this affects immunosuppression are key decision points in managing the posttransplant patient.

While the spectrum of potential infectious pathogens is broad, infectious epidemiology in the immunocompromised population guides targeted prophylaxis strategies. Common posttransplant infections are listed in [Figure 34-5](#). Immunosuppression management in the infected transplant recipient is often challenging, and dependent on the relative immunogenicity of the organ transplanted, the virulence of the pathogen, and the presence or potential of disseminated disease. Minimization of immunosuppression is a mainstay during infectious episodes, but must be balanced with the risk of intervening acute rejection.

Cancer

Chronic immunosuppressive therapy weakens host defenses against neoplastic processes. There is well-established evidence that solid organ transplant recipients of every type have an increased risk of malignancy, both related to immunosuppression and oncogenic viral infections.¹¹⁸ The most common cancers incurred by solid organ transplant recipients are skin cancers, followed by posttransplant lymphoproliferative disease.^{118,119} In this context, posttransplant patients are strongly recommended to have yearly skin examinations by a dermatologist. Screening for malignancy in chronically immunosuppressed patients follows general screening guidelines. Treatment of cancers is driven by site and extent of disease, but in all cases includes reduction in the amount of immunosuppression.

APPROACHES TO TOLERANCE

8 The perpetual goal of clinical transplant immunology is the induction of tolerance. Several advances have been made in identifying potential cellular and molecular targets and pathways on a basic science level, and case reports of maintaining transplant recipients with normal graft function without any or very little immunosuppression are well known. While clinical tolerance remains out of reach in the current era, several potential mechanisms are the focus of research and drug development.

Immunodeletion

Experimental strategies to deplete graft-specific effector T cells have been employed both centrally, in the thymus, as well as in the periphery. These methods take advantage of developing T cells by exposing them to donor-specific antigens at an early stage such that they are deleted to the graft during transplantation. This has been achieved with the use of intrathymic administration of donor-specific antigen such as bone marrow in large animal models of kidney and skin transplantation in conjunction with total lymphoid irradiation.^{120–122} Infusion of intrathymic alloislets in combination with peripheral lymphocyte depletion has also been shown to reverse diabetes in experimental animal models.¹²³ More recently, studies have demonstrated this concept in models of autoimmunity.¹²⁴ These observations suggest that centrally inoculated donor antigen or allopeptides combined with peripheral leukocyte

depletion may lead to the successful induction of tolerance.^{125–127}

Immunoregulation

Postthymic immunomodulatory strategies to induce graft acceptance are often referred to as “peripheral tolerance.” Various approaches exist to induce peripheral tolerance. Since the discovery of CD4⁺ T cells expressing the biomarkers CD25⁺ CD127^{low} and the master gene regulator Foxp3⁺, the field of immunoregulation has expanded to include CD8⁺ regulatory cells, regulatory dendritic cells, and B-regulatory cells.^{100,128–130}

Regulatory T cells (Tregs) have shown the most promise and exert suppressive capabilities over effector-type T cells in various ways.^{131–133} Naturally occurring Tregs make up 1% to 2% of the T-cell repertoire and clonally expand when needed; when removed from immunocompetent individuals the lack of these cells leads to spontaneous autoimmunity in both mouse and man.^{128,134} Their suppressive ability ranges from direct toxic effects on effector cells using granzyme/perforin pathways, to secretion of suppressive cytokines such as IL-10 and TGF- β , to modulation of donor APCs.¹³⁵ Human Treg cells may be isolated, expanded ex vivo, and then reintroduced as therapy in vivo to inhibit chronic rejection responses using human cells and tissue.¹⁰⁰ These findings have allowed Tregs to be introduced into various clinical trials.¹³⁶ Studies have also suggested that existing immunotherapies, such as sirolimus, may also allow for the expansion of these suppressive T-cell subsets.^{137,138} Along with naturally occurring Tregs, inducible Tregs may arise in the presence of donor antigen and may be generated by naïve T cells even in the absence of their naturally occurring counterpart.^{139–141} Tregs have proven to be essential for graft-specific self-tolerance and the expansion of pure populations of these cells will almost certainly be the key to efficient clinical translation.

Immunologic Anergy and Exhaustion

Mechanisms of T- and B-cell anergy are important to the development of graft-specific tolerance. Anergic responses occur within lymphocytes when incomplete activation takes place and all three signals of activation are not fully engaged. Anergic responses have also been associated with regulatory activity. Blockade of accessory molecules and costimulation may also lead to anergic-type lymphocyte responses.¹²¹ T-cell exhaustion occurs when donor antigen load exceeds the activation capacity of recipient T cells thereby overwhelming their activation and clonal expansion capabilities. This concept has been invoked to explain the tolerant effects of liver and multiorgan transplants given the high donor antigen load and chronic stimulation.¹⁴²

Chimerism

The introduction of donor-type immunocytes within a recipient prior to allograft transplantation has been the subject of many investigations over recent years. Combinations of donor and recipient cell types in a single host have been thought to confer a state of operational tolerance to organ allografts. Historically, stable mixed chimerism of donor and recipient cells was a concept limited to the field of bone marrow transplantation. Long-term allograft acceptance without the need for chronic immunosuppression in bone marrow transplant recipients who subsequently received renal allografts from the bone marrow donor encouraged the use of experimental macrochimeric models in the investigation of tolerance.^{143–146} Although bone marrow transplantation is not feasible or appropriate for patients on transplant waiting lists, in vivo models of tolerance utilizing the principles of macrochimerism have demonstrated that it is essential in the tolerogenic potential of mixed chimerism. *Macrochimerism*, has been shown to result in tolerant states but requires the use of cytoreductive therapy to ensure hematopoietic stem cell engraftment.^{147,148} Conditions necessary to achieve stable chimerism include the use of lymphoablative therapy alone or in conjunction with bone marrow infusion. Under these conditions, tolerance to allografts has been reported in rodent and nonhuman primate models.^{149,150} The requirement for lymphoid irradiation has limited the translation of these models to the clinic, and has resulted in a search for effective nonmyeloablative strategies. In an attempt to circumvent the use of irradiation conditioning, many groups have attempted the experimental use of costimulation blockade or T-cell depletion in conjunction with high-dose bone marrow infusions to delete donor reactive cells in the thymus. Results from these nonmyeloablative regimens have proven to be encouraging in mouse models and some large animal models.^{151–155}

Immunomodulating Stem Cells

Recent reports have focused on the suppressive capacity of mesenchymal stem cells (MSCs). MSCs have

shown great promise in both small and large animal models of transplantation.¹⁵⁶ Mechanistically, MSCs have been shown to down-regulate costimulation molecules on APC thereby inducing anergic responses in T cells, keeping APC in an immature, and thus tolerogenic state.¹⁵⁷ Additionally, MSCs have shown the ability to engraft and incorporate into healing tissues. MSCs also inhibit T- and B-cell expansion by dampening the metabolic activity of T cells with the production of indolamine 2,3-dioxygenase which deprives lymphocytes of nutritional tryptophan, inducing cell death.^{156,158} Furthermore, MSCs have also been shown to synergize with standard therapies of costimulation blockade to induce Treg and tolerogenic phenotypes making them a target for future clinical translation.¹⁵⁹

Chapter 35

Organ Procurement and Preservation

Michael J. Englesbe

Key Points

- 1 *Organ donation:* Efforts to expand organ donation are critical to save lives. Organ donation must be done within a regulated system that is deeply rooted in ethical standards of care.
 - 2 *Organ selection:* A careful balance must be maintained between using every viable donor organ and assuring each patient a chance of a successful posttransplant outcome.
 - 3 *Organ procurement techniques:* The organ procurement operation requires coordination of a multidisciplinary team including surgeons, anesthesiologists, nurses, and organ perfusion technicians. Careful procurement and perfusion techniques are mandatory for successful transplant recipient outcomes.
 - 4 *Applied sciences of organ preservation:* Organ procurement and storage results in significant alterations in the homeostasis of the organ. The degree of organ preservation injury contributes to the degree to which normal organ function is delayed or prevented following transplantation. Novel organ preservation techniques aim to mitigate organ preservation injury.
-

Organ transplantation has become a standard of care for end-organ failure. For the majority of recipients, organ transplantation is the only life-saving therapy available. With improvements in outcomes and expansion of indications for both donation and transplantation, the demand for transplantation continues to expand. As of August 2014, there were 123,256 patients waiting for an organ transplant in the United States and 6,315 patients died while waiting for a life-saving organ in the previous year.¹⁻³ In certain regions of the United States, wait times for kidney transplantation exceeds 10 years.

The successful procurement and preservation of these life-saving organs is critical.

ORGAN DONATION

Living Donation

Considering high wait-list mortality and long wait times, early transplant for patients with end-organ failure has significant benefits. For example, patients who receive a kidney transplant prior to initiating dialysis (a preemptive transplant) have a lower rate of allograft failure and mortality and a higher quality of life compared to patients who receive a transplant after beginning dialysis.^{4,5} Living donation facilitates early transplantation and these recipients have better outcomes. The 5-year graft survival of patients receiving a living donor transplant is 79.8% versus 66.6% for recipients of deceased donor transplants.² In the United States, 25.6% of liver and kidney transplants are done with living donor organs, though there is a trend toward less living organ donation, likely related to mounting concerns about donor safety (Fig. 35-1).² In certain cultures, deceased donation is not well accepted and living donation is the primary source of life-saving organs.

In kidney transplantation, living donation is preferable for most recipients. Efforts should be made to encourage potential recipients to secure a living donor organ. Significant advances have facilitated living donation. These include the use of social media to link potential donors with recipients and paired exchange transplant programs. In a paired exchange, a potential recipient secures a willing donor. If this pair is incompatible (blood type or recipient–donor antibody sensitization), then organs are exchanged with another donor–recipient pair (Fig. 35-2). Criteria for living donation are strict. Living donors must be excellent surgical candidates with minimal comorbidities (medical and psychiatric) and must decide upon donation autonomously.

Deceased Donation

In 2013 in the United States, the majority (79.3%) of organs used for transplantation came from deceased donors.¹ In general, organ donors are brain-dead, previously in good health, and free of life-threatening communicable disease. Permission for organ donation is obtained from the patient's next of kin prior to organ donation.

Considering the strong demand for life-saving organs, regulations are necessary to assure fair and equitable distribution across populations and to assure that every suitable organ is procured from every organ donor. Organ donation must be managed by a not-for-profit entity (organ procurement organization or OPO) that is not directly involved in the care of the patient. The OPO as well as the transplant surgical team must be separated from the declaration of death process. Patients who are not brain dead may donate following cessation of cardiac function; this is known as donation after cardiac death or DCD donation.

Declaration of Death

1 In the United States, a patient is considered dead when they have irreversible cessation of brain function (brain dead) or irreversible cessation of circulatory and respiratory functions. The definition of brain death is established locally by hospitals using rules that conform to the *Harvard Criteria*.⁶ Established criteria for brain death are detailed in [Table 35-1](#). The caring physician must rule out potentially reversible causes of coma including hypothermia, shock, sedation, or pharmacologic paralysis. Once the clinical diagnosis of brain death is made, a confirmatory test must be completed before organ donation. Most frequently, nuclear scintigraphy is used to confirm brain death. This test can be done at the bedside, avoiding the transport of the potentially unstable brain-dead patient through the hospital.

Figure 35-1. The number of living and deceased organ donors in the United States.²

In response to the shortage of donor organs, advances have been made to enable the utilization of organs following cardiac death.⁷ These patients have a devastating neurologic injury but do not fulfill criteria for brain death. Family members who intend to withdraw support (inotropes and mechanical ventilation) may wish to consider DCD donation. Following informed consent, ventilator and circulatory support are withdrawn. The patient is declared dead by the caring physician upon cessation of circulation. It is critical that members of the transplant teams are not involved in the process of declaration of death. Each hospital establishes policies and protocols for procurement of DCD donors. In general, the patient is given systemic anticoagulation prior to withdrawal. After the patient is declared dead, 5 additional minutes are usually allowed to elapse prior to organ procurement surgery. If the patient does not reach criteria for death within 60 to 90 minutes, kidney recovery is not pursued. For liver and lung procurement, the maximal acceptable agonal time (time from withdraw to death) is approximately 30 minutes. The transplant surgeon rapidly recovers the organs using a similar technique as brain-dead donor procurement. DCD organs have acceptable but inferior outcomes.⁷

Figure 35-2. Schematic for paired exchange kidney transplantation.

Consent for Donation

Effective efforts to augment organ donation have focused on increasing organ donor registration, usually associated with automobile licensing. A signed and witnessed organ donor card is sufficient indication of the decedent’s wishes to allow organ donation. Despite this declaration, the family’s consent is routinely obtained even when a valid organ donor card is present. Many hospitals have specific team members who seek consent for donation. It is critical that this request is done with great care. Explanation of the organ donation process by an empathetic party not directly involved in the care of the deceased patient yields the highest consent rates.

ORGAN SELECTION

2 Organ quality is closely linked to recipient outcomes. A careful balance must be maintained between using every viable donor organ and assuring each patient a chance of a successful posttransplant outcome. The surgeon should assess general health issues of the donor as well as organ-specific function. Donor age is also relevant, as older organs have inferior long-term outcomes and thus are better suited for older recipients.²

Donor History of Cancer: Potential organ donors should be cured of cancer. Transmission of cancer to the organ recipient results in rapid death related to cancer progression in the setting of severe illness and systemic immunosuppression. Criteria and guidelines for suitability for donation among cancer survivors are well detailed in the literature.^{8,9} Donors with a history of melanoma, leukemia, lymphoma, or small-cell carcinoma are excluded from donation. For most major cancers associated with systemic progression, organ donors should be disease free for 5 years. Some donor cancers have been shown to have minimal risk of transmission to the recipient. These include nonmelanoma skin cancers without nodal involvement, small renal cell and prostate cancers, and many intracranial malignancies that have not recently had intracranial surgical intervention.

Table 35-1 Criteria for Brain Death⁶

All reversible causes of coma excluded
Loss of all function of the entire brain confirmed
■ No pupillary light reflex ■ No corneal reflex ■ No oculoccephalic reflex ■ No spontaneous respirations
Confirmatory diagnostic tests (one must be completed)
■ Electroencephalogram (EEG) with electrocerebral silence ■ No blood flow to the brain on nuclear scintigraphy ■ No flow on four vessel cerebral angiogram

Donor History of Infectious Disease: All donors are screened for communicable disease. The predonation work-up is detailed in [Table 35-2](#). Many donors have been critically ill for many days prior to donation and hospital acquired infections are common. Donors with a recent history of systemic bacteremia are acceptable while donors with fungemia are not. The transplant center needs to follow donor cultures

and make sure that the recipient is appropriately treated.

Donor transmission of HIV, hepatitis B, or hepatitis C can lead to disastrous outcomes in the recipient. Donor history of an ongoing viral infection must be carefully assessed. All donors are tested for an antibody response to HIV. Nucleic acid testing (NAT) for HIV is also done in most cases. NAT testing reduces the “window period” for false-negative test results.¹⁰ Recipients with a previous history of these viruses can receive organs that are infected with them. For example, HIV-positive patients on the waitlist can receive HIV-positive donor organs. Similarly, hepatitis C-positive donor organs without significant liver disease have excellent outcomes in hepatitis C-positive liver transplant recipients.¹¹ With advances in the viral therapies, many hepatitis C-positive patients will no longer have systemic viremia, though they remain antibody positive for hepatitis C. These individuals should not receive hepatitis C-positive organs. Similarly, the HCV viral genotype of the recipient should be considered when deciding to accept a HCV-positive donor organ. Organs from donors with the previous history of hepatitis B infection can transmit the infection to recipients. These organs should be used in recipients who have been immunized against hepatitis B. In liver and kidney transplantation, donors who test positive for hepatitis B core antibody but negative surface antigen can be used in most recipients with excellent results.¹² The recipient does require long-term antiviral therapy.

Other important infectious pathogens can be transmitted during organ transplantation.⁹ Many of these are endemic to specific communities. A cause of death that is suspicious for a communicable disease (such as rabies, encephalitis, etc.) is a red flag against organ donation. The transplant surgeon should discuss infectious disease issues with a transplant infectious disease expert prior to accepting any questionable organs.

Table 35-2 Standard Organ Donor Work-up

■ Consent for donation
■ Confirmation of brain death in brain-dead donors
■ Complete history and physical
■ Determination of “CDC high-risk” status related to social history
■ Comprehensive and serial laboratory evaluation including frequent blood gases, renal function tests, and liver function tests
■ Toxicology screen
■ Cultures
■ Details of hemodynamics and pressor requirements
■ Serologies – Anti-HBcAb, Anti-HCV, Anti-HIV I/II, HIV NAT, Anti-HTLV I/II, HBsAg, Anti-CMV, RPR/VDRL, HBsAb, EBV (IgG), EBV (IgM)
■ Chest X-ray
■ Echocardiogram and EKG
■ Bronchoscopy
■ Blood gas on 100% O ₂
■ Liver biopsy (selectively)
■ Cardiac catheterization (selectively)

Organ-Specific Issues

In addition to a global assessment of the donor, each organ has specific considerations.

- **Kidney** – Primary considerations include donor age, history of hypertension, diabetes, cardiovascular disease, or renal dysfunction. Patients with acute renal failure are suitable donors, though such grafts are more frequently associated with delayed graft function (DGF). Renal biopsy to assess for glomerular fibrosis can aid in graft selection.¹³ High circulatory resistance while on organ preservation pump is associated with inferior outcomes. Kidneys with significant arterial plaque or multiple arteries can be technically more complex to transplant, but rarely do these issues preclude use of the allograft. Efforts should be made to keep the cold ischemia time less than 24 hours.
- **Liver** – Primary considerations include donor age and history of liver disease. Donor elevations in transaminases or bilirubin should be considered; preterminal liver injury is associated with primary nonfunction of the allograft. Allograft size is an important consideration, especially in smaller recipients. A preprocurement liver biopsy is frequently available on patients with risk factors for liver disease. Greater than 30% macrosteatosis and/or parenchymal fibrosis may preclude transplantation. More than a grade 2 traumatic liver laceration generally precludes transplantation. Efforts should be made to keep the cold ischemia time less than 12 hours.
- **Pancreas** – Selection of pancreas allografts must be done with care since recipient complications and allograft failure are relatively common events. Donor age should be less 40 and donors should be free

of major comorbidities and be hemodynamically stable. The pancreas should be soft to palpation (a firm pancreas suggests previous injury) without significant fat infiltration. Donor iliac vessels used for the vascular conduit should be free of atherosclerotic disease. Pancreatic branches from the splenic artery and superior mesenteric artery must be intact (Fig. 35-3). Injury to pancreatic parenchyma precludes use of the organ. Efforts should be made to keep the cold ischemia time less than 12 hours.

- **Heart** – Primary considerations include donor age and history of cardiovascular disease. Predonation work-up includes an echocardiogram; significant structural cardiac disease or abnormal cardiac function precludes donation. Potential donors with risk factors for cardiac disease undergo cardiac catheterization to rule out significant coronary artery disease. The relationship between the donor and recipient body size should be considered. Prior to procurement, the procuring surgeon should examine the beating heart for size and function before the recipient surgeon begins the heart transplant operation. Efforts should be made to keep the cold ischemia time less than 4 hours.
- **Lungs** – Primary considerations include donor age, history of smoking, history of pulmonary disease, and events surrounding death (i.e., aspiration or accident with chest injury). Predonation work-up includes chest X-rays, arterial blood gases, CT scan, and a bronchoscopy with airway cultures. Lung contusions or pneumonia may preclude transplantation. Donors are ventilated on 100% oxygen to assure high blood oxygen levels. The relationship between the donor and recipient body size are considered. At the time of procurement, the donor surgeon performs a repeat bronchoscopy and a median sternotomy to physically inspect the lungs for damage, infection, or underlying lung disease. Efforts should be made to keep the cold ischemia time less than 6 hours.

Figure 35-3. Donor superior mesenteric artery and splenic artery with arterial conduit created from the donor iliac artery.

THE ORGAN PROCUREMENT OPERATION

3 The organ procurement operation requires coordination of a multidisciplinary team including surgeons, anesthesiologists, nurses, and organ perfusion technicians. By convention, transplant centers send their own teams to procure the heart, liver, lungs, and pancreas. The kidneys are procured by one of the other abdominal teams and are shipped to the appropriate transplant center. In most cases, procurement teams travel to the hospital where the donor is admitted; both air and ground transportation is usually required. In some regions, the donors are transported to a centralized procurement facility. This has been shown to reduce costs, travel time, and cold ischemia times.¹⁴ The recipient liver, lung, and heart operations usually begin before organs return to the transplant center; thus continuous communication and coordination are needed between transplant centers and the procurement teams.

Upon arrival to the donor operating room, the transplant surgeon must check the appropriate documentation. This includes identification of the donor, consent for donation, and the donor medical chart. The surgery teams should discuss hemodynamic and anticoagulation management with the anesthesia team.

The surgeons should tuck the arms to facilitate four surgeons being able to work on the donor simultaneously. After induction of general anesthesia, an incision is made from the sternal notch to the symphysis pubis and the abdomen and sternum are opened (Fig. 35-4). Even if the thoracic organs are not being procured, a median sternotomy facilitates exposure for the abdominal operation. The key organ-specific steps are detailed below.

Liver Procurement: The right colon and small bowel are mobilized to expose the entirety of the retroperitoneum, including the intrahepatic vena cava and the aorta. The superior mesenteric artery is encircled at the root of the mesentery close to the aorta. The gallbladder is opened and all of the bile is removed. The left lateral segment of the liver is mobilized and the pars flaccida is inspected for a replaced or accessory left hepatic artery. If an artery is noted, the surgeon must carefully dissect all of the branches from the proximal left gastric artery, staying close to the lesser curvature of the stomach. Failure to properly manage these small branches will result in a postreperfusion hematoma around this artery, potentially causing arterial thrombosis. The porta hepatis is palpated to assess the location of the arteries. If present, a replaced right hepatic artery is noted right and posterior to the common bile duct.

The aorta is dissected at its bifurcation to facilitate proximal and distal control ([Fig. 35-5](#)). The surgeon should assure that there are no renal arteries from the distal aorta or iliac arteries. If there are, the cannulation should occur distal to these arteries to make sure they are flushed. The supraceliac aorta is exposed by retracting the caudate lobe and the left lateral segment of the liver to the right, grasping the crux of the diaphragm, and dividing it with electrocautery. Circumferential control of the supraceliac aorta is not needed, though sufficient exposure for occlusive clamping is a necessity.

When all teams are ready, the donor is given systemic heparin and the aorta is cannulated ([Fig. 35-6](#)). The supraceliac aorta is clamped and the abdominal organs are flushed with cold preservation solution. The inferior vena cava is incised in the chest to drain the perfusate and blood. The liver is surrounded with ice and flushed with approximately 5 L of preservation solution.

Figure 35-4. Exposure for the organ procurement operation.

Figure 35-5. Exposure of the distal abdominal aorta in preparation for aortic cannulation.

Once the flush is complete, the diaphragm is divided leaving a cuff around the suprahepatic inferior vena cava. The infrahepatic inferior vena cava is divided approximately 1 cm above the renal veins. The bile duct and portal vein are divided in the porta (if the pancreas is being used) or the entire head of the pancreas is excised, assuring maximal length of the portal vein. The superior mesenteric artery and the aorta are divided. The surgeon must be sure to not divide the aorta below the orifice of the superior mesenteric artery; the renal arteries are close to the superior mesenteric artery origin and easy to injure. The liver is removed and the portal vein and bile duct are flushed on the back table. Tissue surrounding the liver is removed on the back table to prepare the organ for transplantation.

Arterial anatomy has many variations and, failure to identify variation may jeopardize the transplant operation (Fig. 35-7). On occasion, dissection of the replaced right hepatic artery can jeopardize the pancreas allograft, but usually both teams can agree to an acceptable dissection plane. There are several options for reconstruction of a replaced right hepatic artery. The replaced vessel can be sewn end to end to the gastroduodenal artery. If the replaced right hepatic artery is large, anastomosis to the splenic artery may result in a better reconstruction. A cuff of superior mesenteric artery along with the replaced right hepatic artery can be sewn to the celiac.

Figure 35-6. Aorta cannula securely fixed to the distal abdominal aorta.

Figure 35-7. Variations in hepatic arterial anatomy. Lack of identification of this anatomy may jeopardize the transplant operation.

Figure 35-8. Upon dividing the ureter in the pelvis, a robust amount of periureteral tissue is left around the ureter.

Kidney Procurement: Kidney procurement is the final step in the procurement operation. Kidney procurement is significantly easier if the liver has been removed. If the liver has not been removed and will not be used for transplantation, the portal triad and the right diaphragm should be divided. This results in the liver falling into the right chest, greatly facilitating the kidney procurement.

The supraceliac and the infrarenal aorta should be exposed as described in the liver procurement section. Arterial cannulation should occur distal to all renal arteries, even if they arise from the iliac arteries. The kidneys are mobilized bilaterally out of the retroperitoneum to facilitate packing with ice at the time of cold perfusion. Heparin administration and clamping is coordinated with the other procurement teams. The abdominal viscera are flushed as described in the liver section.

Figure 35-9. Method of procuring the kidneys. Retraction of both kidneys and ureters superiorly while clamping the distal aorta and inferior vena cava together. Division of tissue on the spine, posterior to the great vessels.

The ureters are divided bilaterally in the pelvis and mobilized toward the kidney. The periureteral tissue should be left intact in order to maintain the blood supply to the ureter (Fig. 35-8). The inferior vena cava and the aorta are divided at the bifurcation and the two vessels are clamped together with a single large clamp (Fig. 35-9). The ureters, kidneys, and vessels are retracted superiorly and the tissue posterior to the kidneys is incised. The left renal vein is divided just off of the inferior vena cava, leaving the entire inferior vena cava with the right kidney. The aorta is divided in the midline, providing an aortic cuff to all renal arteries (Fig. 35-10). The kidneys are flushed on the back table and carefully examined for vascular disease and parenchymal lesions. The kidneys are placed in cold storage or on a perfusion pump.

Figure 35-10. Division of the aorta in the midline leaving an aortic cuff around each renal artery.

Figure 35-11. Retraction of the pancreas allograft out of the retroperitoneum during the procurement operation.

Pancreas Procurement: All of the steps necessary for the liver procurement up to the point of perfusion

are completed. The pancreas must be mobilized out of the retroperitoneum with care. This can be done in the cold following flushing, but mobilization prior to flushing allows a careful examination of the organ as well as assuring that the vasculature is ligated.

The short gastric vessels are divided to widely expose the pancreas. The gland is assessed for fatty infiltration or firmness, both of which may preclude transplantation. The retroperitoneal tissue inferior to the pancreas and behind the spleen is incised. The spleen is retracted both anteriorly and medially (Fig. 35-11). The tissue behind the spleen and pancreas is divided until the aorta is reached. The duodenum is divided distal to the pylorus (Fig. 35-12). A vessel loop is placed around the splenic artery. The retrograde cold perfusion is described in the liver section. After approximately 3 L of cold perfusion, the splenic artery is occluded to avoid over perfusion, which may result in edema of the pancreas.

Once perfusion is complete, the pancreas is removed in situ or en bloc along with the liver. The proximal jejunum is divided as it exits the retroperitoneum. It is critical that the root of the mesentery is securely divided with a vascular stapler. Division of the portal vein, the superior mesenteric artery, and splenic artery should be done in communication with the liver surgeon (Fig. 35-13). The iliac artery is procured for creation of the Y graft for the transplant operation (Fig. 35-3). The iliac vein is procured in case an extension graft is needed for the portal vein.

Heart and Lung Procurement: A bronchoscopy is done to examine anatomy, remove secretions and rule out pneumonia. A median sternotomy is performed and a retractor placed. The thymus gland is dissected and the innominate vein is identified in the superior aspect of the chest. The pericardium is incised and stay sutures are placed. The aorta is mobilized, freeing it from the main pulmonary artery and the right pulmonary artery. The superior and inferior vena cava are mobilized (Fig. 35-14). The chest and abdominal teams must agree on where to drain the inferior vena cava. The heart and lung teams must agree on where to drain the left side of the heart. This is usually accomplished by making an incision at the junction of the left atrium and the left superior pulmonary vein, or by transecting the left atrial appendage.

When all teams are ready, systemic heparin is administered. The aortic root is cannulated with a standard needle-tipped cannula. A purse-string suture is placed on the distal main pulmonary artery. A hole is made in the center of this suture and an "L"-shaped cannula is placed in the pulmonary artery. Prostaglandin is administered into the pulmonary artery. The superior vena cava is ligated, the inferior vena cava is incised, an incision is made to vent the heart, and the aortic cross-clamp is placed distal to the coronary perfusion cannula (Fig. 35-15). The heart and lung cold perfusion is started and the organs are surrounded with ice.

Once perfuse is complete, left atrium is divided, leaving an oval cuff of atrial tissue for the pulmonary veins on each lung (Fig. 35-16). The superior and inferior vena cava are divided in collaboration with the liver surgeon. The pulmonary artery is divided, taking care not to damage the left main pulmonary artery. The aorta is divided just distal to the aortic arch and the heart is removed. The lateral and posterior borders of the pericardium are divided, including the posterior wall of the left atrium. The innominate vein is divided and the anterior trachea is identified. The trachea is encircled as high in the chest as possible. The lungs are inflated and the main bronchus and left main bronchus are stapled. The trachea is divided proximal to the staple line and the inflated lungs are removed (Fig. 35-17A,B). The lungs are retrogradely flushed on the back table.

Figure 35-12. Division the duodenum just distal to the pylorus.

Figure 35-13. Pancreas allograft following procurement, with ample length of portal vein, superior mesenteric artery, and splenic artery.

APPLIED SCIENCES IN ORGAN PRESERVATION

4 Organ procurement and storage result in significant alterations in the homeostasis of the organ. The degree of organ preservation injury contributes to the degree to which normal organ function is delayed or prevented following transplantation. Organ preservation injury is largely mediated by ischemia and hypothermia. The duration when the organ is in cold storage is termed “cold ischemia time.” Minimizing this time as well as careful organ preservation is critical for successful outcomes. The core concepts of organ preservation are detailed in the [Table 35-3](#).

Cold ischemia and warm reperfusion cause much of the organ damage. As a result, novel strategies for warm perfusion of organs are being used. These techniques involve perfusion with blood or a blood-like analog with or without oxygenation. These perfusion models are mostly investigational at this time, but offer promise for better organ preservation in the future.

Figure 35-14. Chest exposure for the heart- and lung procurement operation.

Figure 35-15. Steps in the thoracic procurement operation. Clamping in a counter-clockwise manner, beginning with the superior vena cava and ending with the aorta.

- Step 1: Ligation of the superior vena cava, assuring that the azygous is either ligated or the clamp is below the azygous vein.
- Step 2: Division of the inferior vena cava at the pericardial reflection within the chest to drain the right heart adequately. This line of transection must be discussed with the liver surgeon.
- Step 3: An incision to vent the left heart by cutting across the base of the left atrial appendage.
- Step 4: An aortic cross-clamp distal to the coronary perfusion cannula.

Figure 35-16. Preparation of the pulmonary vein cuffs during the lung procurement operation.

Figure 35-17. Stapling of the main bronchus and left main bronchus (A and B). The lungs are then divided between these staple lines.

Several strategies have been developed to mitigate the effects of ischemia on organs obtained following DCD procurement procedures. These include the infusion of antifibrinolytics into the donor organ at the time of flush or transplant.¹⁵ Early reports suggest these strategies result in fewer postliver transplant biliary complications. Another approach is to resume normothermic perfusion of the abdominal viscera following death using an extracorporeal membrane oxygenation (ECMO) circuit. This strategy has several benefits including enabling withdraw of support in the ICU with the family present, resuscitation of the organs following the agonal period, and avoidance of urgency in the procurement operation. A diagram of the ECMO circuit used for DCD procurement is detailed in [Figure 35-18](#).

Machine cold perfusion is now commonly done in clinical transplantation, and in some regions is the standard of care for renal preservation ([Fig. 35-19](#)). Some of the injury during cold ischemia and reperfusion is related to the accumulation of metabolites; perfusion may mitigate these effects by washing out deleterious metabolites and by maintaining patency of the microvasculature of the organ. Machine cold perfusion is now used on nearly 50% of deceased donor kidneys in the United States.¹⁶ Early trials of cold perfusion of high-risk livers and lungs have also been successful ([Fig. 35-20](#)).^{3,17,18} Such strategies may expand usable organs, provide therapeutic interventions directly to the organ during the perfusion process, and rehabilitate damaged organs.

Table 35-3 Key Concepts in Organ Preservation

Prevent thrombosis	- Anticoagulation of the donor - Rapid and complete organ flush following cessation of circulation
Maintain organ structural integrity	- Maintenance of stable configuration of cell membrane lipid bilayer - Cold storage results in conformational changes of cell membrane resulting in cell swelling - Hypertonic preservation solutions mitigate some of these effects
Maintain ionic composition	- Preservation solution electrolyte composition is similar to intercellular composition of Na^+ and K^+ H^+ accumulates as a result of anaerobic glycolysis - Preservation solution buffers H^+ effects
Maintain cellular energy	- Hypothermia reduces metabolism 12-fold - Hypothermia affects the activity of mitochondrial enzymes - Mitochondrial dysfunction results in changes and cellular energy
Reperfusion injury – oxygen free radicals	- The majority of organ injury happens at reperfusion and not during cold ischemia - The sudden availability of O_2 results in the production of reactive oxygen intermediates (O_2^- and $\text{OH}^\cdot$) - Free radicals cause cellular injury – largely through lipid peroxidation - Glutathione protects against peroxidation and is useful in preservation solutions
Reperfusion injury – cytokines	- Tissue injury results in the release of cytokines - Tumor necrosis factor (TNF), interferon-gamma, interleukin-1, and interleukin-8 are released at reperfusion - Cytokine exposure results in the up-regulation of adhesion molecules, resulting in platelet plugging and leukocyte adherence to the endothelium

Chapter 36

Renal Transplantation

Chris E. Freise and Peter G. Stock

Key Points

- 1 The major barriers to successful renal transplantation include ABO compatibility and the human leukocyte antigen (HLA) system.
 - 2 Before a renal transplant is undertaken, histocompatibility of the donor and recipient is determined.
 - 3 Methods to expand the donor pool of kidneys include the use of donation after cardiac death donors and high kidney donor profile index kidneys.
 - 4 The etiology of kidney disease resulting in end-stage failure, and the necessity for transplantation is led by glomerulonephritis, diabetes, and hypertension.
 - 5 The kidney transplant is heterotopically placed in the extraperitoneal iliac fossa.
 - 6 Surgical complications of kidney transplantation include vascular, urologic, lymphocele, and wound problems.
 - 7 Hyperacute rejection is humorally mediated by preformed anti-HLA antibodies. Hyperacute rejection occurs within minutes to hours following reperfusion of the kidney.
 - 8 Acute cell-mediated rejection most typically occurs between 1 week and 3 months following transplantation.
 - 9 Chronic rejection leads to loss of graft function over the course of months to several years.
-

Renal transplantation has evolved to become the preferred therapeutic modality for patients with end-stage renal failure. Improved patient survival and quality of life as compared with dialysis has been established, with cost effectiveness achieved after a minimum of 18 months of allograft function. The importance of minimizing time on dialysis, compounded by the exponential growth of patients on the wait list, has led to several strategies to increase the number of deceased and living-donor organs in an effort to decrease waiting time and mortality on the wait list. These new strategies have been the focus of clinical research in kidney transplantation and will be discussed in this chapter. Other important topics that will be reviewed include immunologic considerations specific to kidney transplantation; preoperative assessment of kidney allograft recipients; the standard surgical approach in kidney transplantation and advances in laparoscopic technology for the donor; current strategies in immunosuppression; management of the technical and immunosuppressive complications; new kidney allocation policies affecting waitlist management; and future trends.

IMMUNOLOGY OF RENAL TRANSPLANTATION

The immunologic response to allografted tissue is well defined and under the influence of both T-cell- and B-cell-derived reactions. The cells and cytokines responsible for rejection vary with time posttransplant (hyperacute, acute, and chronic rejection) and have a differential response to currently available immunosuppressive agents.

1 The major barriers to successful renal transplantation include ABO compatibility and the human leukocyte antigen (HLA) system. In general, renal transplantation is done between ABO-compatible donor and recipients using the same guidelines as for blood transfusion. However, because of the shortage of donors, cadaver kidneys are nearly always used in recipients of identical blood type. Recently, ABO-incompatible living-donor transplants have been performed on an experimental basis secondary to excessive wait times for ABO-compatible deceased-donor transplants.^{1,2}

The HLA system is made up of well-defined antigens present on most cell types that are genetically determined for each patient and are termed the *major histocompatibility complex*. These genes reside on

chromosome 6 and are distributed in a Mendelian fashion to offspring. The HLA system includes several loci, but the most commonly characterized are the HLA-A, HLA-B, and HLA-D regions. Given that each human has two alleles for each locus, there are six potential HLA antigens of clinical significance. These are characterized using tissue-typing techniques and can be used to determine the degree of matching between a donor and potential recipient, that is, one-antigen match to six-antigen match. Improved results of graft survival are seen when the degree of matching reaches the six-antigen level and long-term results may be less favorable with matching to a lesser degree.

Class I antigens include the HLA antigens A, B, and C, whereas class II antigens include the D and DR loci. Class I antigens act as targets for cytotoxic T lymphocytes, and class II antigens are important for antigen presentation. Class II antigens are also responsible for triggering lymphocyte proliferation in the mixed lymphocyte culture system.

2 Before a renal transplant is undertaken, histocompatibility of the donor and recipient are determined. Standard pretransplant workup consists of several assays that will help to determine future compatibility with a potential donor. First, donors and recipients undergo tissue typing, which involves characterization of their respective HLA type. Secondly, recipient serum is tested against a panel of antigens that contain the known HLA types, to identify anti-HLA antibodies. The sensitivity for detecting anti-HLA antibodies continues to improve and newer technology uses single antigen beads to detect antibodies against a specific HLA antigen. The amount of reactivity that a potential recipient has against a panel of HLA antigens is indicative of the degree of sensitization. Based on the number of anti-HLA antibodies detected, a calculated percent reactive antibodies (cPRA) can be estimated. A cPRA of 70% would suggest that the potential recipient would have anti-HLA antibodies against 70% of the potential donor pool. Sensitization to HLA antigens occurs as a result of previous exposure to foreign HLA antigen either from pregnancy, previous blood transfusion, or a previous organ transplant. A patient who is highly sensitized is more difficult to transplant because of the greater likelihood of having antibodies to a potential donor.

The last critical test performed prior to transplantation is commonly known as the *final crossmatch*. This final crossmatch can be performed in several ways. Recipient serum samples collected at different times are mixed with donor lymphocytes in a culture system. This assay will detect preformed cytotoxic antibodies that would result in a hyperacute rejection if the transplantation were performed (see Rejection, later). A more sensitive method of detecting these antibodies uses a fluorescent-activated cell scanner crossmatch and is commonly used when evaluating potential recipients who are highly sensitized or receiving second transplants. Many transplant centers have adopted “virtual crossmatching” based on the detection of anti-HLA antibodies present in a given recipient. The most sensitive technology will be used to detect the presence of anti-HLA antibodies in a given recipient. Based on these antibodies, each recipient will have a list of unacceptable donor antigens. Compatibility with each donor will be determined in the absence of the serum-based final crossmatch by eliminating a potential donor based on the presence of unacceptable antigens. This strategy facilitates an expedited transplant and minimization of cold ischemia times, as it avoids the additional time and expense associated with the serum-based final crossmatch. The use of the virtual crossmatching is particularly beneficial for determining potentially compatible kidneys allocated to highly sensitized recipients, a scenario occurring with increasing frequency as a result of the new kidney allocation algorithm initiated in December 2014. Widespread acceptance of the virtual crossmatch will require further confirmation that all donor antigens are sufficiently identified using the single antigen bead technology. Currently, at least for highly sensitized recipients, most centers will still perform a serum-based final crossmatch to verify the virtual crossmatch result.³

THE DONOR POOL: LIVING DONORS, DECEASED DONORS, DONATION AFTER CARDIAC DEATH

There is marked improvement in graft survival for both living and deceased donors when a transplant can be completed before the initiation of dialysis.⁴ The significantly better outcomes achieved with preemptive transplantation and minimizations of dialysis times have given rise to several strategies to increase the number of available kidneys.

Living Donors

The first long-term success in renal transplantation over 60 years ago involved a live-donor transplant

between twin brothers. The number of living donors has increased significantly in the last few years, in part as a result of the increased use of the laparoscopic technique for donor nephrectomies. For the first time, in 2001 the number of living donors exceeded the number of deceased donors, although deceased-donor transplants still represent the majority of kidney transplants done today.⁵ This trend toward increased live donation may also be the result of the excessive waiting times for deceased-donor transplants, now more than 8 years for blood type O and B recipients in many parts of the United States. Despite initial concerns about the safety and efficacy of the laparoscopic technique for the donor procedure, morbidity and mortality rates (0.03%) remain low and comparable with those of the open technique.^{6,7}

The evaluation of a potential living kidney donor begins with a brief overall assessment of physical condition because potential donors must be in good health with normal kidney function. Diabetes, hypertension, and cardiovascular disease generally rule out a potential donor. ABO is also determined before further workup, because ABO incompatibility has been a relative contraindication to donation. A crossmatch test is usually performed at this time to ensure donor and recipient immunologic compatibility. After this initial screen, a careful medical and psychosocial screen takes place to confirm donor suitability. Following a normal physical examination, further studies should include chest radiography, electrocardiogram, urinalysis, and blood work. During this phase, any conditions that could predispose to later renal insufficiency need to be ruled out. For example, donors from families with a history of type II diabetes are at a significant risk for the development of diabetes and glucose tolerance testing is justified as part of the screening process. A history of renal stones warrants stone analysis to assess likelihood for recurrent stones. Any inherited disorders of kidney disease must also be ruled out, particularly in potential living-related donors when the recipient has polycystic kidney disease.

The psychosocial history is directed at assessing the motivation of the donor, and to ensure that there are adequate resources for the donor to proceed with the surgery and recovery. Many centers require a relationship between the donor and intended recipient, although it is becoming increasingly common to have general members of the public show interest in being evaluated as a donor, with no particular recipient identified. These nondirected donors require the same careful scrutiny as any living donor and the psychosocial evaluation is especially important. The motivation for donation should be clear and not be connected in any way to financial gain. As a further safety measure living donors are also evaluated and counseled by an Independent Living Donor Advocate, usually a social worker, who is not directly involved in the recipient care, and can assess for any psychosocial issues or donor concerns that may interfere with a smooth donation and recovery process. It is also the duty of the physician evaluating the potential donor to review the current statistics on morbidity and mortality. The final testing of a potential donor involves anatomic definition of the two kidneys and is typically done with either a computed tomography angiogram or MR angiogram, both of which avoid the arterial needle stick and catheters associated with a conventional angiogram. The results of these studies are used to detect any anatomic abnormalities that would exclude a donor and to decide which kidney will be removed. In general, the left kidney is favored for transplant because it has a longer renal vein.

Several strategies are currently being considered to increase the frequency of living donation. Potential donors with well-controlled hypertension on a single antihypertensive agent are being considered, although this remains controversial. Controversy also exists regarding the potential reimbursement for living donors, specifically providing financial compensation regarding lost wages during the donation. Consideration is also being given to providing health insurance to living donors for complications related to the donor procedure. The extent of the reimbursement provided to living donors continues to be debated by medical ethicists and transplant professionals. Finally, a national exchange system is currently being designed that matches living donors who were incompatible with their intended recipient (either because of ABO incompatibility or a positive crossmatch test) with other recipients with incompatible living donors. Such exchange systems have already been successful on a regional and national level, and extending this to a single national system will permit many more successful exchanges and further expand the living donor pool. The creation of a single national exchange system is still a work in progress. The advantage of having greater numbers of donor and recipient pairs in the “pool” is to increase the likelihood that a highly sensitized recipient will be able to be matched to a compatible donor. There have also been some preliminary attempts at including compatible donor and recipient pairs in the pool, with their consent, in an effort to facilitate transplantation of highly sensitized recipients.⁸

Deceased Donors

3 Procurement of kidneys from brain-dead deceased donors has not increased at the same pace as the rapid growth of the national wait list (Fig. 36-1). Although most deceased donors are brain dead, there has been an increased use of kidneys from donors who do not meet the strict definitions of brain death but have cardiopulmonary support withdrawn because of a severe brain injury or high spinal cord injury, with little hope of living without the use of ongoing mechanical ventilation and/or the possibility of existing in a persistent vegetative state. Organs are recovered after withdrawal of support, once the heart stops beating, hence the terminology of *donors by cardiac death* or *DCD donors*. Usually support is withdrawn in a controlled setting so that the time of warm ischemia and poor organ perfusion can be minimized. Minimizing the time from cessation of the heart to perfusion of organs with preservation fluid requires an experienced procurement team, and the successful use of these organs is dependent on rapid procurement. Although the use of livers from DCD donors appears to be associated with a higher incidence of biliary tract complications following transplantation, kidneys procured from DCD donors are proving to be an important source of donor kidneys.⁹ Several studies from the United States and Japan have demonstrated comparable graft success between kidneys procured from DCD donors and brain-dead donors, although the incidence of initial delayed graft function is higher in DCD kidneys.¹⁰ The percentage of DCD donors in the United States has progressively increased over the last decade and presently represents about 10% of deceased donors.

Placement of deceased-donor kidneys is guided by a series of complex allocation rules established by the United Network for Organ Sharing (UNOS). Unfortunately, the number of people being added to waiting lists continues to be significantly greater than the number of people being removed following transplantation. UNOS has recently implemented a new kidney allocation algorithm, although it is unlikely that it will have a significant impact on the overall waiting times for deceased kidney transplants, now approximating 7 to 8 years for certain blood types in several parts of the country. Nonetheless, there are some significant changes which will impact the allocation process. Donor kidneys are now assigned a kidney donor profile index (KDPI) score, the lower the score the better predicted survival of the kidney (better quality kidney). The new allocation system attempts to match the predicted longevity of the deceased-donor organ quantified by the KDPI with the estimated posttransplant survival (EPTS) of the recipient. The top 20% of kidneys (KDPI scores less than 20%) will be transplanted to recipients with longest EPTS (top 20%). In the new allocation scheme, the highest KDPI kidneys (KDPI >85%) will be allocated to recipients who have consented to receive an expanded criteria donor. Highly sensitized patients will receive a significant number of allocation points, so if in the rare event that a compatible kidney becomes available (based on the virtual crossmatch), that kidney will be allocated to the compatible highly sensitized recipient. Highly sensitized recipients with cPRA's of 99% or 100% will get access to the regional and national lists respectively to increase the chances of finding a compatible kidney. Finally, waiting times will be backdated to the time of the initiation of dialysis, although patients can still be listed when the glomerular filtration rates drop below 20 mL/min.¹¹

Figure 36-1. The growth in the number of patients awaiting transplant (A) has exceeded the relatively stagnant rate of deceased-donor kidney transplants leading to progressively increasing waiting times over the last decade. Living donors had a slight increase early in the last decade, which may be in part due to the introduction of the laparoscopic donation procedure, but rates of living donation are currently flat (B). (Adapted from: SRTR and OPTN Annual Data Report, 2012, available at: http://srtr.transplant.hrsa.gov/annual_reports/2012/Default.aspx. Accessed July 15, 2015)

Further Strategies for Increasing the Number of Donor Kidneys

Many of the unique approaches for increasing the number of potential donors have come from Japan, where cultural beliefs have limited the number of available deceased-donor transplants. Several groups have reported successful kidney transplantation across ABO blood group barriers, using aggressive pretransplant immunosuppression, plasmapheresis to decrease anti-ABO titers, and in some cases splenectomy.^{1,2} This strategy has been implemented with increasing frequency in the United States as a result of the marked increases in the waiting times for blood group O and B recipients.¹² While this strategy may be effective for living-donor pairs that are ABO incompatible in the United States, it is more common to place these ABO-incompatible pairs into one of the kidney exchange programs.

For donor recipient pairs that are incompatible due to a positive crossmatch, an important strategy currently being implemented in the United States, as well as internationally, involves the use of desensitization protocols to facilitate transplantation across a known positive anti-HLA crossmatch. These protocols may involve pretransplant infusion of gamma globulin in the recipient to bind circulating antibody, plasmapheresis of the recipient to remove circulating antibody, and/or the use of agents, such as rituximab, to decrease antibody production. These protocols could potentially impact the increasing number of sensitized patients on waiting lists who have little hope of finding a compatible donor.¹³ Lastly, a hybrid approach for the highly sensitized recipient with a crossmatch-incompatible donor could involve finding a kidney that is “less incompatible” through an exchange program, and then converting the positive crossmatch to a compatible crossmatch with desensitization techniques. Further strategies have recently been implemented to expand the number of kidneys procured from deceased donors. In addition to the use of kidneys from DCD donors described earlier, transplant centers have considered using kidneys from donors that are less than optimal, previously designated as expanded criteria donors (ECD). In the previous allocation scheme, these donors were between age 50 and 59, and had two out of three other clinical feature: history of hypertension, died of a cerebrovascular injury, or had a terminal creatinine of greater than 1.5 mg/dL. Additionally, any donor over age 60 was considered an ECD. These kidneys clearly had a shorter survival compared to younger, healthier donors and therefore potential recipients were required to give consent to receive these kidneys before transplant. The advantage to certain patient groups who were predicted to do poorly on dialysis (i.e., older patients or patients with diabetes) was an increased overall patient survival if they received a

timely transplant with an ECD kidney, rather than wait a prolonged time on the list. In the newer allocation scheme, ECD kidneys are now defined as KDPI >85%. In the new allocation system, kidneys with KDPI >85% will be allocated to an expanded list (regional versus local) in order to increase organ utilization and minimize the chance of discard. The increased use of “kidney pumping” may help to determine the quality of these ECD kidneys by observing flow rates on the pump, and may also decrease the rates of posttransplant delayed graft function.¹⁴

THE TRANSPLANT PROCEDURE

Recipient Preoperative Assessment

4 The etiologies of kidney disease resulting in end-stage failure and the necessity for transplantation are led by glomerulonephritis, diabetes, and hypertension (Table 36-1).¹⁵ Because of the high incidence of cardiovascular disease associated with many of these conditions, most notably diabetes, a careful assessment of the cardiovascular status of the potential recipient is critical. For patients at risk, this assessment should include at a minimum an echocardiogram and an exercise or pharmacologic stress test as a screen for reversible ischemia requiring cardiac catheterization. Controversy remains with regard to the accuracy of noninvasive studies in terms of identifying significant disease of the coronary arteries, particularly in diabetic patients. Nonetheless, for most centers this remains the standard screening strategy, and updated studies should be obtained within 1 year of the transplant procedure. If either coronary artery bypass or stenting has taken place in preparation for renal transplantation, follow-up angiograms and/or stress tests should be repeated within 1 to 2 years of the actual transplant. If stenting of the coronary arteries is required, patients with drug eluting stents will commonly require clopidogrel (Plavix) for an extended period of time. Although controversial, many centers will proceed with transplantation while recipients are on Plavix, within 6 months of the stenting procedure.

Table 36-1 Etiology of Renal Disease as Indications for Renal Transplantation, Ranked in Order of Prevalence

Diabetes mellitus (types I and II)
Hypertension
Polycystic kidney disease
IgA nephropathy
Chronic glomerulonephritis
Focal sclerosis
Systemic lupus
Membranous glomerulonephritis
Pyelonephritis
Focal segmental glomerulosclerosis
Congenital obstructive uropathy
Nephritis
Alport syndrome
Hypoplasia, dysplasia
Wegener granulomatosis
Postinfectious glomerulonephritis
Obstructive uropathy
Hemolytic uremia
Membranoproliferative glomerulonephritis
Goodpasture syndrome
Membranous nephropathy
Analgesic nephropathy
Prune belly syndrome
Medullary cystic disease
Henoch–Schönlein purpura
Nephronophthisis
Scleroderma
Sickle cell anemia
Amyloidosis
Oxalosis

Although the evaluation of potential recipients is focused on the assessment of cardiovascular status, further studies must exclude malignancies and infections that would contraindicate transplantation and immunosuppression. Potential kidney recipients who are infected with hepatitis C should be evaluated by a hepatologist to determine the risks of immunosuppression causing progression to end-stage liver disease. Potential kidney recipients with evidence of advanced liver disease should be evaluated for a combined liver and kidney transplant. For patients with less advanced liver disease, consideration could be given to treatment with newer antiviral drugs before proceeding with kidney transplantation to provide the opportunity for viral clearance.¹⁶ Kidney transplantation was previously contraindicated in people with HIV infection secondary to concerns of exacerbating an already immunologically compromised state. Recent advances in antiretroviral therapy and the ability to provide effective prophylaxis against opportunistic infections has prompted several centers to perform transplantation in people with end-stage renal disease and HIV infection. Early results suggest that progression of HIV to AIDS has not been seen following transplantation and immunosuppression, with early allograft success rates comparable to those in non-HIV-positive recipients.¹⁷ Potential patients with a previous history of tuberculosis or conversion to purified protein derivative positivity should be evaluated for active disease.

Colonoscopy, mammography, and Pap smear should be performed as dictated by age-specific standard guidelines. For most malignancies, a disease-free interval of 5 years is recommended before kidney transplantation. Controversy exists about pretransplant waiting times for certain malignancies, such as early stage breast cancer or prostate cancer, and some centers will not require any pretransplant waiting. Similarly, pretransplant wait times are probably not necessary for nonmelanoma skin cancers and early stage renal cancers. For patients with congenital abnormalities as the cause of renal failure, a complete workup of the genitourinary systems is necessary, including urodynamics and voiding cystourethrograms. These studies are particularly important in children with end-stage disease resulting from posterior urethral valves, to ensure that the bladder will serve as an adequate conduit for the kidney transplant. For patients with severe reflux disease and chronic pyelonephritis, native nephroureterectomy may be required to prevent posttransplant infection secondary to chronic reflux into the native ureters. For patients with inadequate bladder capacity and function, pretransplant reconstructive procedures such as ileal augmentation or ileal conduits may be required.

For patients with suspected clotting disorders based on a previous history of thromboembolic events (frequent clotting problems with dialysis access) or diseases associated with an increased frequency of clotting disorders (i.e., lupus), a hematologic workup is necessary to determine the necessity for anticoagulation at the time of the transplant. The length of time for anticoagulation is dependent on the severity of the clotting disorder and a history of a previous thrombotic event. This workup should include a determination of serum levels of protein C, protein S, anticardiolipin antibody, factor V Leiden, antithrombin III levels, and the G20210 A prothrombin gene mutation.

Living-Donor Nephrectomy: Open and Laparoscopic

A living kidney donor operation is a unique surgical procedure for two reasons. First, the donor has no medical reason to be in the operating room, and the process is driven only by his or her willingness to help another person with the gift of donation. Second, the removed tissue must be in perfect condition because it will be reimplanted into the recipient. These two features, therefore, necessitate that the donor operation is done safely and done well. The original donor operation was done through a generous flank incision, allowing for good exposure and careful dissection of the renal vessels. Unfortunately, this flank approach generally left a large incision, with its accompanying morbidity, pain, and sometimes adverse cosmetic result. The development of the laparoscopic procedure to remove kidneys has revolutionized the field, although its initial introduction was met with trepidation because of concerns over donor safety. With the explosive growth and dissemination of this procedure, it has now become the standard for donor nephrectomy.

The procedure is most commonly done through a transperitoneal approach, although some surgeons prefer to remain retroperitoneal. Once the operative space is expanded with carbon dioxide gas and the scope is inserted, two to three additional ports are placed to allow for the passage of instruments to dissect the kidney (Fig. 36-2). Some centers also favor the use of a gastight “hand-port,” which allows placement of the surgeon’s hand in the operative space to assist in exposure and to have available if sudden bleeding is encountered. Once the kidney vessels are transected and the vessel stumps are controlled by laparoscopic staples, the kidney can be removed through a 2- to 3-in incision, which can be placed in a position that leaves minimal scarring and avoids cutting muscle tissue. Most commonly

this is via a Pfannenstiel incision, and recently the use of natural orifice approaches has been described. Additionally, some centers have adopted the use of a robotic assisted technique, to facilitate the dissection of important vascular structures. Donors who undergo the laparoscopic procedure typically have reduced pain medicine requirements, have a slightly shorter hospital stay, and are able to return to their usual activities sooner.^{6,7}

The safety of this relatively new procedure has been established, in addition to the demonstration that kidneys recovered through a laparoscopic approach function as well as kidneys removed in an open operation. There has been an increased interest in live donation, coincident with the introduction of the laparoscopic procedure, suggesting that this procedure has removed some of the disincentives of the donation process.

Recipient Operative Procedure

The kidney transplant is heterotopically placed in the extraperitoneal iliac fossa. Although this is a less technically demanding procedure than either liver or pancreas transplants, attention to detail is imperative to optimize immediate graft function and avoid technical complications resulting in loss of the kidney transplant.

5 The operation is initiated by exposure of the iliac fossa through a curvilinear incision and can be done on either the right or left side. The incision extends from 1 cm above the symphysis pubis to approximately 2 cm medial to the anterior iliac spine (Fig. 36-3). The fascia is divided along the lateral border of the rectus sheath, and the contents of the peritoneal cavity are reflected cephalad and medially, exposing the iliac vessels in the retroperitoneum. Lymphatics overlying the iliac vessels are ligated and divided to prevent the development of lymphoceles. In males, the spermatic cord is secured with a vessel loop and can be retracted away from the operative field. In females, the round ligament is suture ligated and divided. The inferior epigastric artery and vein are typically divided to prevent potential compression of the transplanted ureter. Placement of a mechanical retractor should avoid compression of the iliac artery and vein as well as the femoral nerve to prevent neuropraxias.

The living- or deceased-donor kidney is inspected for the presence of multiple vessels, duplication of the urinary collecting system, and parenchymal abnormalities. The artery and vein are dissected from surrounding structures to provide the necessary length for transplantation. In the case of multiple arteries, a decision must be made as to whether to perform ex vivo reconstruction to achieve a single implantable conduit versus implanting the vessels separately. This decision is in part dependent on the quality of the recipient vessels and an assessment as to whether the anastomosis of multiple vessels directly into the recipient would require an unacceptable period of warm ischemia to the kidney. In general, in an adult the anastomosis of the renal artery and vein are performed in an end-to-side fashion to the external iliac vessels, although occasionally the presence of atherosclerotic disease requires transplantation to the common iliac vessels. In children who weigh less than 20 kg, or for third transplants in adults, an intraperitoneal approach is used and the vascular anastomoses are frequently performed to the aorta and inferior vena cava. For kidneys from deceased donors, a Carrel patch of aorta is used to prevent stenosis and to provide a common patch for multiple arteries. Warm ischemia time should be minimized to prevent delayed graft function. Ensuring adequate intravascular volume and stable hemodynamics at the time of reperfusion is extremely important to achieve optimal function of the transplant.

Figure 36-2. A: The laparoscopic donor procedure is performed with the donor in a lateral position, typically using three to four ports, with extraction of the kidney through a 6- to 8-cm incision. B: Preoperative computed tomography angiogram revealing the arterial and venous anatomy. C: Intraoperative photograph of laparoscopic view of right kidney just prior to transection of the renal vein. The artery has already been divided.

The reimplantation of the ureter is most frequently performed through an extravesicular technique. Following positioning of the revascularized kidney in the iliac fossa and assurance of hemostasis, the ureter is shortened to permit a tension-free anastomosis with adequate blood supply to the distal ureter. In men, the ureter is placed under the spermatic cord to prevent ureteral obstruction. The bladder is distended with an antibiotic solution to identify a suitable area for ureteral implantation on the dome of the bladder, and a cystotomy is made at this site. An anastomosis between the mucosa of the bladder and transplanted ureter is constructed using an absorbable suture to prevent stone formation. A second layer of the bladder musculature is closed over the distal portion of the ureter to prevent reflux during micturition.

Figure 36-3. A: Curvilinear iliac fossa incision used for the kidney transplant recipient procedure. B: Vascular anastomoses completed between the recipient external iliac artery and vein and donor renal artery and vein. *Insets:* ureteral anastomosis performed using the external ureteroneocystostomy technique.

There are alternative techniques to reimplant the ureter, including the Politano–Leadbetter transvesical ureteroneocystostomy. This technique involves tunneling the ureter through the bladder wall from the inside of the bladder. This technique is still preferred by some surgeons who believe the long-term prevention of reflux is superior with the transvesicular approach. However, this technique

requires a second cystotomy, and posttransplant hematuria is more common than with the extravesicular technique. A third technique for ureteral implantation in recipients with normal native ureters is ureteroureterostomy over a double-J stent. In general, this technique is reserved as a salvage procedure for reimplantation of transplanted ureters with distal strictures secondary to ischemia. It can also be used as a primary technique if there are questions regarding the blood supply to the distal ureter at the time of transplant. This technique is preferred if the donor ureter was damaged or inadvertently stripped of its blood supply at the time of procurement but is dependent on the availability of normal native ureters to serve as an adequate conduit. The routine placement of a double-J stent is center dependent, with some centers reserving placement of the stent for challenging extravesicular anastomosis to poor quality bladders.

The surgical procedure has changed little over the last 60 years, with the exception of limited reports of implantation of the kidney with the use of a robotic-assisted laparoscopic approach. The purported advantage is smaller incisions, which appear to have an advantage in obese patients, avoiding some of the frequent wound complications. Widespread adaptation of this technique has not occurred.¹⁸

COMPLICATIONS

Early Graft Dysfunction

Most kidneys begin to function immediately after implantation, especially in the case of a living donor. When the initial function results in only a slow drop in serum creatinine, the diagnosis of slow graft function is made. When dialysis is needed in the first week because of poor function, the diagnosis of delayed graft function is made. Delayed graft function typically occurs in 15% to 30% of deceased-donor transplants. The diagnosis of slow graft function or delayed graft function is important to establish because other problems, such as rejection, vascular occlusion, or ureteral obstruction, can also result in low urine output and need for dialysis. These other causes must be eliminated before the diagnosis of slow graft function or delayed graft function can be made.

In the immediate postoperative period, careful attention to fluid status is critical. In cases of immediate graft function, fluid orders should include replacement for urine output as well as a maintenance fluid rate. This approach ensures that the patient does not become volume depleted and compromise perfusion to the new kidney. In cases of delayed graft function, fluid should be restricted and dialysis instituted when electrolyte imbalance or fluid overload are evident.

A decrease in urine output in the early postoperative period requires immediate diagnostic and therapeutic intervention. A stepwise algorithm to assist in diagnosing the etiology of oliguria is shown in [Figure 36-1](#). Once mechanical obstruction of the indwelling Foley catheter has been excluded by irrigation, the volume status of the patient should be assessed, preferably with a central venous pressure line or pulmonary artery catheter. Fluid replacement to restore intravascular volume should be initiated in the volume-depleted patient.

Radiologic evaluation using various imaging techniques is required if urine output remains low in the face of adequate volume status. Ultrasonography is most helpful to diagnose ureteral obstruction caused by technical complications at the anastomosis or fluid collections that may be obstructing the ureter by extrinsic compression. With the addition of duplex and color Doppler imaging, blood flow to the kidney can be evaluated and technical problems with the vessels can be assessed. Nuclear medicine techniques are also valuable for assessing renal function. Technetium 99m diethylenetriamine pentaacetic acid (DTPA) and iodine-131 iodohippurate (Hippuran) are the two major radionuclides used in the evaluation of renal allograft function. DTPA renal scans evaluate the vascular flow pattern of the kidney as well as the gross anatomy of the ureter and bladder. Scans are performed over 30 minutes, with uptake of contrast within 6 seconds indicating adequate flow to the graft. Peak activity in the parenchyma should be reached within 2 minutes, followed by a gradual decline in radioactivity in the renal parenchyma and an increase in radioactivity in the urinary collecting system and bladder. Iodine-131 iodohippurate scans are more sensitive in evaluating renal function. Peak activity is also reached in 2 to 4 minutes, with gradual decline over the next 30 minutes. In rejection, acute tubular necrosis and drug toxicity poor uptake and poor excretion are the typical findings with a nuclear medicine scan.

If these imaging techniques do not provide an explanation for poor urine output, the diagnosis of delayed graft function is made. Immunosuppression can then be adjusted to minimize or avoid the calcineurin inhibitors, which can prolong the recovery from delayed graft function, and also to initiate antibody therapy to protect the kidney from rejection. The combination of delayed graft function and

early rejection is clearly associated with worse outcome in the long term, and an early biopsy of the kidney that is functioning poorly is helpful to diagnose rejection and guide therapy.

Technical Complications

6 Most surgical complications are experienced in the immediate postoperative period. The two main types of complications can be classified as vascular and urologic.

Renal artery thrombosis is a rare complication occurring in about 1% of transplants. The risk of this complication is higher with size mismatch of donor renal artery and recipient internal iliac artery when an end-to-end anastomosis is performed, in kidneys with multiple renal arteries, in kidneys traumatized because of rough handling, and in the presence of an unidentified renal artery intimal flap. Sudden loss of urinary output, not the result of an obstructed Foley catheter or inadequate vascular volume, should necessitate a workup with duplex Doppler ultrasound. Loss of signal is indicative of no flow to the kidney. Alternatively, a nuclear medicine renal scan is informative, with lack of isotope uptake by the kidney indicating no blood flow. Prompt return to the operating room for correction of a technical problem is imperative, but often the diagnosis is not made quickly enough to salvage the kidney.

Renal artery stenosis occurs in up to 15% of transplanted kidneys. Difficult-to-control hypertension should suggest the possibility of stenosis. Diagnosis with renal duplex ultrasound followed by arteriography to better define the anatomy and degree of stenosis should be done before operative repair or angioplasty. Initial success rates for both methods are similar (75% to 80%), but the restenosis rate following angioplasty is not well defined. Anastomotic strictures respond less well to angioplasty and probably should be repaired by operative intervention.

Algorithm 36-1. Stepwise approach to the management of decreased low urine output posttransplant.

Aneurysms that occur in the renal artery are either pseudoaneurysms at the anastomotic site or mycotic aneurysms secondary to bacterial or fungal infection. A rapidly expanding, tender pulsatile mass in the region of the kidney suggests a mycotic aneurysm. Arteriography is confirmatory for diagnosis. Treatment consists of appropriate antibiotics and removal of the transplanted kidney.

Venous complications are less frequent, with thrombosis occurring in 1% to 4% of transplants. Causative factors include intimal damage during retrieval, kinking at the iliac vein anastomosis, or pressure secondary to a lymphocele, urinoma, or hematoma. Occasionally, severe rejection can result in venous occlusion. Heparin infusion for incomplete occlusion and transplant nephrectomy for complete occlusion are the indicated therapies. Occasionally, graft salvage is possible if the diagnosis is made

before progression of clot into the kidney itself. The classic sign of new onset hematuria may be an early hint of a renal vein problem and should lead to an ultrasound.

Urologic complications include ureteral obstruction, urinary fistula, or bladder leak. These complications all present with decreased urine output and a rise in serum creatinine. With a urine leak, pain in the region of the transplant may be severe. Mechanical obstruction of the Foley catheter must first be eliminated. Ureteral obstruction occurs in 1% to 9% of transplants, and diagnosis can be made with ultrasonography demonstrating hydronephrosis. A leak is usually diagnosed with a nuclear medicine renal scan. Further definition of a leak or stricture can be obtained via an antegrade pyelogram (Fig. 36-4). Early obstruction of the transplant ureter at the site of the bladder anastomosis may respond to internal stenting. Late strictures usually require reoperation, and urine and blood polymerase chain reaction for the polyoma virus should be done in that circumstance, because polyoma viral infection can lead to ureteral stricture. The surgical correction of a ureteral stricture may require reimplantation of the ureter into the bladder, the creation of a Boari flap, or the use of the recipient's native ureter for a ureteroureterostomy (Fig. 36-5).

Figure 36-4. Percutaneous nephrostogram revealing a urine leak from the ureterovesical anastomosis.

Figure 36-5. A: Reconstruction of a stenotic donor ureter, showing resection of the stenotic segment and mobilization of the bladder. B–D: A Boari flap is constructed from a tabularized segment of bladder wall and anastomosed end-to-end to the proximal donor ureter.

IMMUNOSUPPRESSION, REJECTION, AND IMMUNOSUPPRESSIVE COMPLICATIONS

Immunosuppression

Major advances in the ability to block immune-mediated destruction of the kidney have taken place in the past few years, resulting in a significant decrease in the incidence of acute rejection and improvement in long-term allograft survival rates.¹⁵ This advance is the result of numerous agents that have been added during the past decade to the immunosuppressive armamentarium of prednisone, azathioprine, and cyclosporine A. These agents include tacrolimus, mycophenolate mofetil, sirolimus, and everolimus (mTOR inhibitors), anti-interleukin-2 receptor blockers, antithymocyte globulin (a polyclonal anti-T-cell agent), rituximab (an anti-CD20 monoclonal agent), and most recently costimulatory blockade with CTLA4-Ig. The addition of various newer drugs targeting different pathways in the alloimmune cascade has permitted the development of regimens that are less dependent on the calcineurin inhibitors or prednisone.¹⁹

Newer strategies in the immunosuppressive pipeline are targeted to block: costimulatory pathways; signaling pathways that activate T cells and T-cell proliferation; and trafficking and recruitment of immune cells. The most promising biologic agents targeted to block the costimulatory pathways include a second-generation CTLA4Ig (LEA29Y), a humanized anti-CD11-a (anti-LFA1), and a humanized anti-B7.1/B7.2. Promising agents designed to block T-cell activation and proliferation are the inhibitors of the Janus protein tyrosine kinase (JAK3) and the leflunomide analog FK778. Finally, drugs to block the trafficking and recruitment of immune cells are antagonists against the chemokine receptors CCR1, CXCR3, and CCR5. The chemokine antagonists have been effective in experimental transplantation and will likely be transitioned to clinical trials in the near future.²⁰

Rejection

7 Hyperacute rejection is extremely rare and is humorally mediated by preformed anti-HLA antibodies. Hyperacute rejection occurs within minutes to hours following reperfusion of the kidney, whereas classic cell-mediated rejection typically does not occur until 1 to 2 weeks after the transplant. In hyperacute rejection, the anti-HLA antigens bind to the vascular endothelium of the kidney transplant, resulting in activation of the complement cascade and rapid graft thrombosis. The kidney appears blue-black with poor tissue turgor despite adequate blood flow. The characteristic histologic appearance includes the triad of polymorphonuclear leukocytes in the glomerular capillary loops, fibrin deposition, and platelet thrombi. The kidney cannot be salvaged, and a transplant nephrectomy is necessary. The presence of anti-HLA antibodies should be detected in the pretransplant crossmatch, and with the sensitivity of current immunologic assays, hyperacute rejection is usually a result of technical or clerical errors in the crossmatch procedure. A more common and less intense form of humoral rejection occurring within a few days of transplantation is a result of reactivation of memory B cells following reexposure to alloantigen. The histologic findings are defined by positive C4d staining on vascular endothelium, although lymphocytic infiltrates consistent with classic cell-mediated rejection can be present. Treatment of this aggressive rejection can include plasmapheresis, the anti-B-cell agent rituximab (anti-CD20 monoclonal antibody), and polyclonal antilymphocyte preparations (antithymocyte globulin).

8 Classic acute cell-mediated rejection typically occurs between 1 week and 3 months following transplantation. Most patients with rejection episodes present with decreasing urine volumes and increases in serum creatinine values. Low-grade fever and allograft tenderness may be present, but significant physical symptoms frequently are absent. Immediate workup of increasing serum creatinine should be initiated, beginning with an ultrasound to rule out ureteral obstruction or technical vascular complications as the cause of the deteriorating function. Similarly, toxicity from calcineurin inhibitors needs to be determined by checking drug levels. A percutaneous kidney biopsy is performed to confirm rejection. The severity of the rejection episode is based on the presence of lymphocytes in renal tubules (tubulitis) and vascular endothelium (vasculitis). Mild rejection is generally treated with pulse

corticosteroids and maximizing the maintenance immunosuppression to ensure therapeutic levels of calcineurin inhibitors. More severe rejection with both tubulitis and vasculitis, as well as steroid-resistant rejection, is treated with antilymphocyte antibody preparations, most frequently with rabbit polyclonal antilymphocyte preparations. If the rejection episode occurred while the patients had therapeutic drug levels, maintenance therapy is frequently altered following the antibody therapy. For example, if maintenance therapy consisted of cyclosporine A, the calcineurin inhibitor could be switched to tacrolimus. Other potential strategies include the addition of an mTOR inhibitor to the immunosuppressive regimen, particularly for cases where there is evidence of calcineurin inhibitor toxicity on biopsy.

9 Each rejection episode takes a toll on long-term function of the kidney transplant. Even well-controlled acute rejection episodes initiate a cascade of events leading to interstitial fibrosis and proliferative changes affecting the vascular endothelium. These histologic and progressive degenerative changes are classified as chronic rejection or chronic allograft nephropathy. These changes lead to loss of graft function over the course of months to several years. Current strategies minimizing calcineurin inhibitor nephrotoxicity are being used to prolong function in kidneys with these chronic changes and involve the addition of TOR inhibitors to replace the calcineurin inhibitors. It remains unclear whether the marked decrease in acute rejection episodes, from greater than 50% to less than 20% observed in the past 5 years, will translate to better long-term function of transplants. Nonetheless, it is evident that immunosuppression strategies minimizing prednisone and calcineurin inhibitors are providing safer and more effective immunosuppression for kidney-transplant recipients while decreasing long-term toxicities associated with immunosuppression.

Immunosuppressive Complications

It would be naive to assume that the intensification of immunosuppressive regimens resulting in decreased acute and chronic rejection rates can be accomplished without sequelae. Infections and malignancy remain significant complications associated with long-term immunosuppression and are the driving force for drug-minimization strategies. Early infections during the perioperative period are commonly iatrogenic and involve bladder infections or intravenous catheter use. Higher doses of immunosuppressive drugs used in the early postoperative period predispose patients to these infections and emphasize the importance of maintaining sterility during Foley catheter placement and insertion of intravenous catheters. Pneumonia related to mechanical ventilation and poor postoperative inspiratory effort can occur in the early postoperative period, and early incentive spirometry should be encouraged to decrease the potential for this infection. Wound infections are relatively uncommon, although diabetes and obesity are both associated with a much higher incidence of wound complications. Weight reduction to achieve a body mass index of less than 35 is strongly recommended to facilitate the operative procedure and minimize the risks of wound complications, particularly in the recipient with diabetes mellitus.

Cytomegalovirus (CMV), a herpesvirus, remains a problematic infection in the immunosuppressed patient and can become symptomatic 1 to 2 months following the transplant. CMV-seronegative patients who receive a kidney from a CMV-seropositive donor are at the highest risk for infection, although prophylaxis with acyclovir or ganciclovir is generally provided for all recipients for a period of 3 to 6 months following the transplant. Despite prophylaxis, activation of CMV can occur, accompanied by fever, malaise, pneumonia, gastrointestinal distress, or dysfunction of the kidney transplant. The effective treatment of blood- or tissue-invasive CMV has been one of the major advances in the management of kidney transplant patients within the past two decades. What was a life-threatening disease in the early era of solid organ transplantation can today be effectively managed with oral antibiotics.

Prophylaxis against *Candida albicans* with fluconazole and *Pneumocystis carinii* with trimethoprim-sulfamethoxazole is also part of most management strategies posttransplant. Other potentially life-threatening opportunistic organisms that can affect the chronically immunosuppressed transplant recipient include *Aspergillus*, *Cryptococcus*, *Listeria*, *Nocardia*, and *Mycobacterium*.

More potent immunosuppression regimens used in the current era have been associated with the emergence of polyoma or BK virus, a previously rare infection that may cause graft loss in up to 5% of infected patients. Reduction in immunosuppression is necessary to prevent progression of viral tubulitis. There has been some experience with the use of leflunomide, ironically an immunosuppressive agent, but with an active metabolite, A77 1726, that has substantial antiviral activity in vitro and in animals. Another potential medication, cidofovir, is a nucleotide analogue that inhibits viral DNA polymerase but

unfortunately is also nephrotoxic, and its in vivo efficacy has not been proved. Probably the best method to prevent graft loss due to polyoma is the use of monitoring of urine and serum levels of BK virus, with lowering of immunosuppression when early evidence of polyoma is detected.

Patients with a previous history of active tuberculosis or conversion to purified protein derivative positivity should receive appropriate prophylaxis for 6 months to 1 year following the transplant procedure.

More potent immunosuppression regimens will also have an impact on the development of neoplasms following transplantation.²¹ Skin cancers are the most common malignancy following transplantation, with more than 90% being squamous or basal cell cancers. The incidence of skin cancers is staggering, with 50% or more of white recipients ultimately developing lesions. The immunosuppressed patient also has a higher incidence of nodal spread, and educating the patient about the importance of avoiding direct sun exposure is essential. Other malignancies that have a particularly high incidence in transplant recipients include non-Hodgkin lymphomas and carcinomas of the anogenital areas. The etiology of anogenital carcinoma is related to the presence of human papilloma virus. Although there have been no prospective trials to date, there is some evidence that TOR inhibitors are advantageous in the setting malignancies as the preferred immunosuppressive agent based on their antiproliferative qualities. Conversion to mTOR inhibitors and minimization of calcineurin inhibitors is a strategy that has been used with increasing frequency in the scenario of malignancies following transplantation.

Figure 36-6. Comparison of graft survival and graft half-life ($t_{1/2}$) in 1992 and 2002 for different donor types (age >60 years in 1992 group, age >50 years with hypertension, elevated creatinine, or donor death from cerebrovascular accident in 2002 group). There has been an improvement in survival for all donor types, with the best long-term results with living-donor kidneys. ECD, expanded criteria donor; LD, living donor; SCD, standard deceased donor.

Posttransplant lymphoproliferative disease is the second most common form of malignancy in transplant recipients and is associated with Epstein–Barr virus. These lymphoproliferative syndromes present as a spectrum of pathology, extending from polyclonal lymphoproliferation to monoclonal B-cell lymphomas. Polyclonal disease has been managed by decreasing or withdrawing immunosuppression, whereas progression to monoclonal lymphomas has required chemotherapy. CD20-positive lymphomas have been successfully managed with rituximab, an anti-CD20 antibody, with no significant side effects.

CURRENT RESULTS AND FUTURE TRENDS

Over the past three decades, progressive improvement has been made in patient and graft survival, independent of donor source. This progression is best shown in [Figure 36-6](#) for the period of time spanning 1992 to 2002. Overall graft survival, as well as the half-life of the graft, improved incrementally for live-donor transplants, standard deceased-donor transplants, and even deceased-donor transplants using suboptimal or expanded criteria donors.¹⁵ This change is related to improved organ preservation, perfected operative technique, and most important, improved immunosuppressive agents. Current 1-year actuarial graft survival rates for living and deceased-donor transplants are 94.8% and 88.9%, respectively.²² These remarkable 1-year results continue to be overshadowed by the specter of late graft loss due to chronic rejection. This problem remains unsolved in renal transplantation, and future improvement in long-term survival will be achieved only when the mechanisms of this process are understood.

The exponential growth in waiting lists compounded by the ongoing critical shortage of organs will continue to stimulate creative means of increasing both the living- and deceased-donor pools. Expansion in the number and types of immunosuppressive agents has resulted in marked decreases in the incidence of acute rejection, which it is hoped will translate to prolongation in the long-term function of kidney transplants. Newer strategies in immunosuppressive regimens that minimize nephrotoxic cyclosporine and tacrolimus by adding nonnephrotoxic agents will also benefit the long-term function of transplanted kidneys. The effect of ischemia-reperfusion injury on both early and late graft function, as well as its impact on the development of chronic rejection and transplant glomerulopathy, is an area of active research, and potential therapeutic interventions to minimize this injury are being evaluated. The induction of tolerance to foreign antigen remains the “holy grail” of transplantation. A paucity of tolerizing regimens have been applied clinically, although the use of donor bone marrow or stem cells will likely have a future role in achieving the elusive goal of transplantation tolerance.

Chapter 37

Hepatic Transplantation

Theodore H. Welling

Key Points

- 1 The main indication for liver transplantation is end-stage liver disease, defined as the clinical scenario in which a pathologic process or multiple processes have resulted in a damaged liver that has minimal function and no potential for recovery.
 - 2 The Organ Procurement and Transplantation Network uses the Model of End-stage Liver Disease score as a method of prioritizing liver transplant recipients. The Model of End-stage Liver Disease score is an integer value based on three objective laboratory studies: creatinine, bilirubin, and the international normalized ratio.
 - 3 The degree of preoperative debilitation and the complexity of the operative procedure make complications following hepatic transplantation very common.
 - 4 Approximately 2% to 4% of transplanted livers function so poorly in the immediate postoperative period that death is likely in the absence of retransplantation, a condition referred to as primary nonfunction of the allograft.
 - 5 For reasons that are not completely understood, liver transplant recipients require less immune suppression than patients with other types of allografts, such as heart, lung, and kidney recipients.
 - 6 Typical acute rejection in liver transplant recipients is usually cell mediated.
 - 7 Chronic rejection is characterized by relentless immune attack on small bile ducts. Histologically, small bile ducts are obliterated or completely absent, termed *vanishing bile duct syndrome*.
 - 8 The patient survival rate following liver transplantation in the United States at 1 year is more than 85% for adults and nearly 90% for children.
-

Liver transplantation has evolved over the past four decades to be the standard treatment for patients with a variety of acute and chronic liver diseases. The first successful liver transplant was performed on a moribund child with a hepatoma by Dr. Thomas Starzl at the University of Colorado in 1967.¹ This child lived more than a year before succumbing to recurrent tumor. Over the next 12 years, liver transplants continued to be performed at a modest rate. Despite 1-year survival rates of less than 50%, it was clear that some patients benefited from the procedure.

In 1979 cyclosporine was introduced into clinical organ transplantation by Sir Roy Calne.² Almost immediately 1-year patient survival rates jumped to over 70%. As a result, liver transplantation programs began to appear worldwide. Today more than 10,000 liver transplants are performed annually in the United States, and survival rates exceed 85% at 1 year and 70% at 5 years, primarily varying on liver disease indication.^{3,4}

The clinical expanse of liver transplantation is now primarily limited by the availability of suitable donor organs. Every year more patients are listed for liver transplantation than receive transplants. In the future it is likely that this problem will worsen because of the large number of individuals with chronic hepatitis C infection, a significant portion of whom will eventually develop cirrhosis and hepatocellular carcinoma (HCC), and the expanding numbers of patients with either HCC or nonalcoholic steatohepatitis (NASH).⁵ Attention continues to be focused on methods to increase the available supply of livers for transplantation. Notable efforts to improve the supply of available organs include the work by the Department of Health and Human Services, which recently took up the cause of organ donation vigorously. This effort, termed the Organ Donation Breakthrough Collaborative,⁶ focused on improving the success rate of organ donation efforts at the hospitals that have most potential organ donors nationwide. The Center for Medicare and Medicaid Services also joined the effort by declaring specific Conditions of Participation for all hospitals that treat Medicare patients in the United States.⁷ This effort focused on encouraging methods of approaching donor families that have been shown to be optimally effective.

Many other methods to increase the number of donor livers are currently being practiced. These methods include the utilization of older liver donors, steatotic donor livers, the development of techniques to allow a single liver graft to be split into two grafts, and the utilization of liver grafts from donors that donate after cardiac death (DCD). Many centers have continued the development of safe surgical techniques that allow healthy, living volunteers to donate a segment of their liver to a recipient in need of a liver transplant.^{8,9}

GENERAL INDICATIONS FOR HEPATIC TRANSPLANTATION

1 The most common indication for liver transplantation is end-stage liver disease. The term *end-stage* refers to the clinical scenario in which a pathologic process or multiple processes have resulted in a damaged liver that has minimal function and no potential for recovery. The diagnosis of end-stage liver disease is made primarily on the basis of clinical findings. Additional information about the etiology of the liver disease and thus its natural history can often be obtained by supplementary investigations including serologic studies and histologic examination of a liver biopsy specimen. It is important that potential liver transplant recipients are evaluated by a hepatologist and surgeon with expertise in end-stage liver disease, because many other diseases may present similar clinical pictures.

The severity of liver disease in an individual is highly variable, from mild cirrhosis and no symptoms to severe decompensation resulting in deterioration of mental status and frank renal failure. The rate of progression of liver disease from a functional state to invalidism and death is variable and may be rapid or may take several years. The challenge facing liver transplant professionals is to identify patients who will benefit from transplantation. Hepatic transplantation may result in wonderful and dramatic results, but at the same time it is always a high-risk procedure. In situations in which patients enjoy full performance status, and are only minimally symptomatic, transplantation is an inappropriate therapeutic measure. A liver transplant is a major surgical procedure on a profoundly ill individual with unavoidable risk that also requires chronic, lifelong immunosuppression. Despite advances in immunosuppressive medications developed over the past four decades, immunosuppression remains a treatment that induces a state of vulnerability in the recipient by virtue of the fact that the recipient's natural resistance to infection and malignancy is compromised. It is thus critical that patients be carefully selected who will benefit from the procedure.

Table 37-1 MELD and PELD Score

MELD score = $0.957 \times \text{Log}_e (\text{Creatinine [mg/dL]}) + 0.378$ $\times \text{Log}_e (\text{Total bilirubin [mg/mL]}) + 1.120$ $\times \text{Log}_e (\text{INR}) + 0.643$
PELD score = $0.436 (\text{Age younger than 1 year} = 1, \text{Older} = 0)$ $- 0.687 \times \text{Log}_e (\text{Albumin [g/dL]}) + 0.480$ $\times \text{Log}_e (\text{Total bilirubin [mg/mL]}) + 1.857$ $\times \text{Log}_e (\text{INR}) + 0.667 (\text{Growth Failure} = 1)$

2 How is it possible to properly select patients and properly time transplantation so that the benefit of transplantation is assured? In 2002, the Organ Procurement and Transplantation Network began using the Model of End-stage Liver Disease (MELD)¹⁰ score as a method of prioritizing liver transplant recipients. The MELD score is an integer value based on three objective laboratory studies: creatinine, bilirubin, and the international normalized ratio (INR) (Table 37-1). This has been adapted to pediatric patients as the Pediatric End-Stage Liver Disease (PELD) utilizing the variables in MELD along with albumen instead of creatinine and including age as well as the presence of growth failure (Table 37-1). Analysis done by the Scientific Registry of Transplant Recipients (SRTR) has shown that patients with MELD scores of less than 15 have a mortality rate on the waiting list that is less than the mortality rate of the transplant procedure in the same population.¹¹ This suggests that patients with a MELD score of less than 15 do not receive an absolute survival benefit from transplantation whereas patients with higher MELD scores have the potential to receive a survival benefit with liver transplantation. In other words, there is no evidence that patients who are very ill from liver disease do not benefit from liver transplantation, but patients who have stable, mild liver disease should not receive a transplant until their disease has progressed to a more severe state.

Surprisingly, MELD more accurately predicts mortality than clinical factors that were previously thought to be ominous signs of reduced (6 months or less) survival. Such factors, including the presence

of ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, or variceal hemorrhage, do not add to the predictive value of MELD.¹⁰ This finding may be related to the difficult nature of accurately quantifying clinical variables in registry databases or to the fact that MELD is such an accurate way of measuring functional hepatic capacity that no additional clinical variables are more relevant.

As will be discussed later, the transplant community has agreed upon certain exceptions to the MELD score for patients with chronic liver disease. It is generally supported that patients with diseases such as HCC, hepatopulmonary syndrome (HPS), primary oxaluria, and familial amyloidosis benefit from additional MELD points by regional review boards. Other diseases or complications such as portal vein thrombosis or portopulmonary hypertension (PPHTN) remain less clear and are handled on a case-by-case basis.¹²

Table 37-2 Urgent Listing Criteria for Liver Transplantation

Status 1A:	<i>FHF</i> (encephalopathy within 8 wks of liver disease and ICU status with ventilator dependence, renal replacement therapy, INR >2.0, or acute Wilson disease) <i>Hepatic artery thrombosis of liver transplant</i> (AST >3,000 U/mL and INR >2.5 or acidosis within 7 d) <i>Primary nonfunction of liver transplant</i> (AST >3,000 U/mL and INR >2.5 or acidosis within 7 d) <i>Anhepatic state</i> (graft removal for any reason)
Status 1B:	Age <18, chronic liver disease in ICU with MELD/PELD >25 plus one of the following: ventilator dependence, GI bleeding, renal replacement therapy, GCS <10

The improved ability to predict mortality for patients with liver failure allowed the development of national allocation policies that direct livers to those patients that will benefit. Importantly, the implementation of the MELD system of liver allocation from deceased donors has been associated with a decrease in the death rate on the waiting list.¹³ Further refinements of our understanding will undoubtedly occur as improved long-term follow-up data on waiting list mortality become available and as quality of life considerations are added to the analysis.

These considerations apply to the chronic forms of liver failure, but not to the important emergency decisions about transplantation that must be made when a patient presents with fulminant hepatic failure (FHF), which is defined as the progression from good health to liver failure with hepatic encephalopathy within 8 weeks. Without transplantation, the mortality rate for FHF is approximately 75%.¹⁴ Death often occurs rapidly once patients progress to stage II (confusion), stage III, (stuporous), or stage IV (unresponsive) hepatic encephalopathy. In these cases, the decision to perform transplantation is based on clinical grounds. Current liver transplant allocation policy allows for the rapid transplantation of patients with fulminant hepatic failure. These patients can be listed as “status 1A,” (Table 37-2) which gives them higher priority for available livers than patients with chronic liver disease who are prioritized based on MELD score.

CONTRAINDICATIONS TO LIVER TRANSPLANTATION

The number of absolute contraindications to hepatic transplantation has steadily decreased during the past several years as experience with the procedure has increased. Many clinical situations once considered to be absolute contraindications for transplantation are now either no longer considered to be contraindications or to be only relative contraindications. A thrombosed portal vein is no longer a contraindication to transplantation because techniques have been devised to effectively deal with this condition (see Liver Transplantation: Surgical Procedure).¹⁵ The presence of juvenile-onset diabetes mellitus formerly precluded transplantation. In current practice, this is not usually the case, depending on the patient’s physiologic status at the time of evaluation. Similarly, advanced age causes concern, but in most centers the physiologic state of the patient is a more important consideration than the chronologic age.

The inability to withstand the operative procedure, usually for cardiovascular or pulmonary reasons, is still generally considered to be a contraindication to liver transplantation. Specific examples include patients with depressed ejection fraction secondary to ischemic cardiomyopathy, significant pulmonary

hypertension, and significant chronic obstructive pulmonary disease. Cardiac disease that is not amenable to percutaneous therapy poses a particular problem because these patients are frequently unable to withstand a corrective cardiac procedure because of their severe liver disease. In highly selected patients it may be possible to perform combined heart and liver transplantation or combined lung and liver transplantation.

Recent intracranial hemorrhage is almost always a contraindication because during the liver transplant procedure, coagulopathy is often present along with significant alterations in arterial blood pressure. The risk of a catastrophic exacerbation of intracranial bleeding during a transplant is therefore high in this setting. However, the meaning of “recent” is not defined in either the transplant or the neurosurgical literature. Profound, irreversible neurologic impairment is also considered to be a contraindication. Active substance abuse remains a contraindication, as is the lack of the necessary social support network.

HIV infection, long considered a contraindication, is no longer an absolute exclusion due to the development of highly effective antiretroviral therapies.^{16,17} Active sepsis or untreated infection and active extrahepatic malignancy continue to be contraindications.

Although renal insufficiency increases the risk of liver transplantation, it is not a contraindication. Patients who have hepatorenal syndrome (HRS) frequently experience recovery of renal function following liver transplantation. However, patients who have longstanding hepatorenal failure and patients with known renal parenchymal disease requiring renal replacement therapy are often best served by combined liver/kidney transplantation.

DISEASE-SPECIFIC INDICATIONS AND OUTCOMES

While the MELD score assessment plays a critical role in evaluating and listing patients that might benefit from liver transplantation, patients that develop liver disease-specific complications, regardless of MELD, are also appropriate to consider liver transplantation. Some of these complications along with other liver-specific metabolic diseases are listed in [Table 37-3](#). Hepatitis C is currently the most common disease for which liver transplantation is currently performed in the United States (33%) ([Fig. 37-1](#)). Alcoholic liver disease, NASH, and cholestatic liver diseases are the next most common ranging from 10% to 14% of cases. However, this trend is believed to be changing with a greater proportion of liver transplants being performed for NASH ([Fig. 37-2](#)).⁵ Outcomes following liver transplantation are best for pediatric patients with biliary atresia, while patients with cholestatic liver diseases experience the best survival among adults ([Fig. 37-3](#)). Patients with hepatitis C or HCC experience worse survival secondary to disease recurrence although recent advances in hepatitis C antiviral therapy may change this trend.¹⁸ Disease-specific indications, outcomes, and considerations will be discussed in the following sections.

Alcoholic Liver Disease

Excessive alcohol consumption can lead to several hepatic abnormalities, ranging from alcoholic hepatitis to steatosis, hepatic fibrosis, and cirrhosis. Alcoholic liver disease was once thought to occur only in individuals who consumed large quantities of alcohol over long periods of time. It has recently become recognized that even moderate amounts of alcohol consumption can induce liver injury, suggesting that hereditary and or environmental factors are probably important. Hepatitis C viral infection, found in 15% to 25% of patients with alcoholic liver disease, appears to exacerbate alcohol-induced liver injury and vice versa.

Table 37-3 Liver Disease Complications and Liver-Specific Metabolic Diseases

Complications:
Ascites
Encephalopathy
Refractory variceal hemorrhage or portal gastropathy
HCC
Hepatopulmonary syndrome (HPS)
Portopulmonary hypertension (PPHTN)
Fulminant hepatic failure (FHF)
Metabolic diseases:
Wilson disease
Alpha-1 antitrypsin disease
Familial amyloidosis
Urea cycle enzyme deficiencies
Glycogen storage disease
Tyrosemia
Primary oxaluria

When liver transplantation emerged as a standard therapy for end-stage liver disease in the 1980s, intense debates occurred surrounding the issue of offering liver transplantation. There were two broad areas of concern. First, many were skeptical that patients with a history of longstanding alcoholism would be able to successfully comply with the rigorous long-term medical treatment required of patients who receive lifelong immunosuppression. On a broader level, concern was expressed that scarce societal resources should not be used to treat patients with “self-induced” diseases. With more experience in this area, it has been recognized that the incidence of recidivism after transplantation is low, and both short- and long-term results in this category are as good as for nonalcohol-related categories. It has also become understood that determining worthiness for receiving a lifesaving organ by making a judgment about past behavior is neither ethical nor possible.

Today, the same methods of determining suitability for transplantation are used for patients with alcoholic liver disease as with other diagnoses with one proviso. Alcohol-induced liver injury frequently regresses following cessation of alcohol consumption as long as cirrhosis is not yet present. Patients with a history of recent alcohol abuse should therefore be observed for a minimum of 6 months to ensure that their hepatic dysfunction is not reversible. In addition, all patients with a history of substance abuse must be evaluated by individuals with expertise in addiction and found to have good insight into their past self-destructive behavior and a stable social support network for the posttransplant phase.

Figure 37-1. Percentage of liver transplants for each etiology. (From O’Leary JG, Lepe R, Davis G. Indications for liver transplantation. *Gastroenterology* 2008;134:1764–1776.)

Figure 37-2. Changing incidence of liver transplantation for NASH, HCC, and Hepatitis C. (From O’Leary JG, Lepe R, and Davis GL. Indications for liver transplantation. *Gastroenterology* 2008;134:1764–1776.)

Viral Hepatitis

Most patients who become infected with hepatitis B develop an immunologic response to the virus that results in complete viral clearance. Patients who do not clear the hepatitis viral antigen may persist as carriers or may develop chronic hepatitis, which progresses to fibrosis and cirrhosis. In the 1980s, transplantation for hepatitis B was associated with universal recurrence of viral infection posttransplant and survival rates were poor. Fortunately, transplantation for this indication was revolutionized by the development of effective posttransplant prophylaxis using long-term, high-dose, hepatitis B immune globulin and the nucleoside inhibitors lamivudine or entecavir.^{19,20} Today, outcomes for transplantation for hepatitis B-induced liver failure, while varying based on genotype, are equivalent to or better than those for other conditions.²¹

Hepatitis C has become the most common etiology among patients receiving liver transplants.⁵ Antiviral therapy using pegylated interferon and ribavirin for early hepatitis C infection has been demonstrated to have clinically important responses seen in over half of patients treated. However, complete clearance of HCV from the serum can only be achieved in a minority of patients which is largely related to viral genotype and whether significant toxicities to therapy develop.^{22,23} Fortunately, multiple new anti-HCV medications have now been FDA approved and show much improved complete response rates and improved tolerability. These recent developments will serve to change the landscape for patients with chronic HCV, eliminating the need for transplantation in many cases, and offer new options to treat HCV recurrence following transplantation.¹⁸

Figure 37-3. Disease-specific survival following liver transplantation. (From Roberts MS, Angus DC, Bryce CL, et al. Survival after liver transplantation in the United States: a disease-specific analysis of the UNOS database. *Liver Transpl* 2004;10:886–897.)

Following liver transplantation, recurrence of HCV hepatitis in the transplanted liver occurs universally unless the virus was eradicated pretransplant with therapy.²⁴ Although some patients experience an indolent course, most patients experience a more rapid progression to liver failure once cirrhosis has developed posttransplant. These patients can progress to end-stage liver failure within 6 months. Short-term results of transplantation for this disease are comparable to those for the other noninfectious conditions. However, approximately 25% of patients develop recurrent cirrhosis within 5 years posttransplant, and long-term survival is less likely compared with patients who do not have hepatitis C infection. Use of livers from donors of increased age are thought to contribute to poorer results in hepatitis C patients.²⁵ Treatment of recurrent hepatitis C posttransplant is presently being attempted with some of the new antiviral therapies available and clinical trials underway.^{18,26} Despite recurrence, transplantation appears to provide a substantial and worthwhile survival benefit to most

patients with hepatitis C.

Hepatocellular Carcinoma and Other Hepatic Malignancy

Cirrhosis is a major risk factor for the development of HCC, and the majority of HCCs develop in patients who have cirrhosis. Curative resection is unsafe in the setting of advanced cirrhosis, and it does not eliminate the high likelihood of recurrent malignancy. Because most patients with HCC die of liver failure, rather than metastatic disease, it was reasoned that transplantation would be potentially curative. This approach yielded poor survival rates, and during the early 1990s primary hepatic malignancy was considered a contraindication to liver transplantation by many centers. This circumstance changed when Mazzaferro et al.²⁷ reported an 85% 4-year survival rate for patients who had cirrhosis and either stage I or stage II HCC (Table 37-4). Transplantation is now considered standard therapy for HCC and cirrhosis if there is no evidence of extrahepatic disease, vascular invasion, and if the tumor burden does not exceed stage II (single tumor ≤5 cm in diameter, or 2 to 3 tumors, none >3 cm in diameter). While some advocate transplantation of patients with larger tumors,^{28,29} this practice is still controversial due to concerns of overall lower disease-free survival. Many centers now adopt a downstaging strategy with local regional therapies such as radiofrequency ablation (RFA) or transarterial chemoembolization (TACE) to bring patients down to stage II in order to list for liver transplantation.³⁰ Transplantation is clearly not beneficial in the presence of known positive nodal or distant metastases (stage IV disease). To create relative equality for a scarce resource, MELD allocation points are standardly allocated to HCC patients meeting the Milan criteria so as to minimize waitlist dropouts due to disease progression and at the same time not over utilize donor livers from the remainder of the recipient candidate pool. However, in recent reviews of outcomes of liver transplantation as reported by the SRTR,⁴ the adjusted 3-year survival rate for HCC patients was 74% and was statistically lower than non-HCC recipients (81%) during the MELD era while at the same time one of the lowest waitlist drop-off rates and higher transplant rate among other disease indications for transplantation,^{4,31} suggesting that the allocation policy may need further refinements.

Table 37-4 TNM Classification and Staging of Hepatocellular Carcinoma

Classification	
T1	One nodule ≤1.9 cm
T2	One nodule 2.0–5.0 cm; two or three nodules, all <3.0 cm
T3	One nodule >5.0 cm; two or three nodules, at least one >3.0 cm
T4a	Four or more nodules, any size
T4b	T2, T3, or T4a plus gross intrahepatic portal or hepatic vein involvement on imaging
N0	No evidence of regional nodal involvement
N1	Regional (porta hepatitis) nodal involvement
M0	No evidence of metastatic disease
M1	Evidence of metastatic disease
Stage Grouping	
Stage I	T1
Stage II	T2
Stage III	T3
Stage IV A1	T4a
Stage IV A2	T4b
Stage IV B	Any N1, any M1

From Facciuto ME, Rochon C, Pandey M, et al. Surgical dilemma: liver resection or liver transplantation for hepatocellular carcinoma and cirrhosis. Intention-to-treat analysis in patients within and outwith Milan criteria. HPB (Oxford). 2009 Aug;11(5):398–404.

Other primary tumors of the liver include hepatoblastoma, cholangiocarcinoma, and primary sarcoma. Hepatoblastoma occurs primarily in children with resection or transplantation being used as potential curative options.³² Transplantation is utilized for patients who are unresectable because of bilobar disease or hilar location. Hepatoblastoma can respond partially to chemotherapy, but complete and sustained tumor regression is uncommon. Patients are often treated with chemotherapy until the time of transplantation to prevent extrahepatic growth prior to the definitive treatment. Hepatoblastoma is relatively unique among liver tumors in that long-term survival has been reported even in children who have had distant metastatic spread.

Cholangiocarcinoma has historically been considered a contraindication to transplantation because 5-year survival rates have been reported at less than 20%. Recently, success similar to other recipients has been reported for patients who have limited disease (<2.5 cm, no lymph node disease) and have received neoadjuvant chemotherapy and radiation along with aggressive staging prior to transplantation.^{33,34}

Although there are anecdotal reports of long-term survival following transplantation for primary sarcoma of the liver, the majority of experiences indicate that transplantation is not a curative therapy for this condition. Liver transplantation is generally not appropriate for patients who have secondary (metastatic) hepatic malignancy, because long-term survival rates are very poor due in part to the observation that immunosuppression promotes tumor growth. The possible exception to this rule is patients who have metastatic carcinoid or neuroendocrine tumor that is limited to the liver. These tumors can progress very slowly and local cure of the primary tumor is frequently possible. While it is still controversial when compared to other standard therapies, long-term disease-free survival following liver transplantation is possible in selected circumstances.³⁵

Nonalcoholic Fatty Liver Disease (NAFLD)

NAFLD may be the most common liver disease in the United States. It has a high incidence in obese patients and those with adult-onset diabetes mellitus. The disease resembles alcoholic liver disease, but patients do not report a significant history of alcohol use. The degree of hepatic injury varies from benign elevations of serum hepatic transaminases in association with hepatic steatosis or steatohepatitis to fibrosis and cirrhosis. A majority of patients previously classified as having cryptogenic cirrhosis probably have longstanding steatohepatitis. It is estimated that at least two-thirds of the obese population in the United States has hepatic steatosis and close to one-fifth have steatohepatitis.³⁶ Patients who develop cirrhosis and progress to end-stage liver disease are appropriate candidates for liver transplantation. Recurrence of steatohepatitis leading to graft dysfunction is possible. Recipient diabetes or obesity appears to be independent negative prognostic indicators for survival after liver transplantation.³⁶

Fulminant Hepatic Failure

Acute hepatic failure, defined as the development of altered mental status, coagulopathy and hepatic dysfunction within 8 weeks of the onset of an acute hepatic disease, is a rare, but lethal disease.^{14,37} There are over 2,000 cases of acute hepatic failure per year in the United States. The mortality rate approaches 80% in patients who do not receive liver transplants. The causes of acute hepatic failure include viral hepatitis, toxins such as aflatoxins from the poisonous mushroom family *Amanita phalloides*, acute fatty liver of pregnancy, acute Budd–Chiari syndrome, and drug toxicities. Drug toxicities include both idiosyncratic reactions and drugs with predictable toxicity when taken in excess. Drugs that have been reported to induce idiosyncratic liver failure include isoniazid, halothane, valproate, disulfiram, and phenytoin, among many others. The over-the-counter analgesic, acetaminophen, causes dose-dependent hepatic failure and is now the single most common cause of acute hepatic failure in the United States.

The most generally accepted criteria for transplantation of patients with FHF were described by the group at the King's College hospital in London, England (Table 37-5).³⁸ While the King's College criteria has been separately validated in other studies, more recent studies have begun to evaluate whether other scoring systems may have improved abilities to measure severity of illness. MELD has come under recent investigation in this regard and has been found to be additive to the King's College criteria in predicting outcome following FHF.^{39,40} The current United National Organ Sharing (UNOS) listing criteria for patients with FHF is in Table 37-2. The outcomes following transplantation have shown overall higher perioperative mortality, compared to other diseases, with overall similar long-term survival (Fig. 37-3).³

Biliary Atresia

Biliary atresia is a congenital disorder of infants, occurring in about 1 of 15,000 births, that is characterized by biliary obstruction resulting from obliteration or discontinuity of the extrahepatic biliary system resulting in progressive hyperbilirubinemia, cirrhosis, and hepatic failure. Other anatomic anomalies can also be coassociated with this disorder such as a preduodenal portal vein. The etiology is not completely defined yet is the most common indication for hepatic transplantation in pediatric patients. Standard treatment includes creation of a portoenterostomy (Kasai procedure), if this can be done before 3 months of age. After this point, success rates diminish markedly. Response to the

portoenterostomy procedure is highly variable. Patients may develop cirrhosis within the first 6 months of life or live into their twenties before developing synthetic dysfunction and portal hypertension. Approximately 75% of children will require transplantation by 6 years of age.

Table 37-5 King’s College Criteria for Liver Transplantation

Acetaminophen	Nonacetaminophen
pH <7.3	PT >100 s (INR >6.5)
Or all three of: Grade 3–4 encephalopathy PT >100 s (INR >6.5) Cr >3.4 mg/dL	Or any three of: Age <10 or >40 y Etiology (non-A, non-B hepatitis, halothane, drug reaction, Wilson disease) Period of transition from jaundice to encephalopathy <7 d PT >50 s (INR >3.5) Total bilirubin >17.5 mg/dL

It is critical that these patients are managed by an experienced pediatric gastroenterologist so that the correct window for effective transplantation can be identified and so they receive appropriate attention to their specialized nutritional needs. Specifically, deficiencies of fat-soluble vitamins that depend on bile for absorption are common and treatable. Transplantation is appropriate when children manifest growth and nutritional failure, when ascites develops, and when portal hypertension progresses to the point of variceal hemorrhage. Recurrent cholangitis is also thought to be an indication for liver transplantation. Transplantation for this population overall has had excellent results with >85% 10-year survival being achieved in the United States.⁴¹ Factors that have been associated with improved survival include living donor transplants and older recipient age. Patients with significant growth failure generally have poorer outcomes.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC), thought to be autoimmune in nature, is characterized by gradually increasing serum bilirubin levels, progressive fatigue, and cirrhosis. Early stages of the disease are usually asymptomatic, and disease progression may evolve over 20 years. Treatment with ursodeoxycholic acid appears to slow the progression of the disease, but immunosuppression does not. It was once thought that PBC does not recur, however, histologic analysis has shown that the incidence of recurrence is approximately 15% within 5 years of transplantation.⁴² Eventual progression to graft failure requiring retransplantation is possible, though rare.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is an autoimmune disease that is characterized by gradually progressive inflammation of the biliary tree, eventually resulting in cirrhosis. It is associated with ulcerative colitis, but removal of the colon does not affect progression of the disease. In most cases, colectomy for associated inflammatory bowel disease is done after successful transplantation because the failing liver makes the patient a poor candidate for a large abdominal procedure. PSC is also associated with the development of cholangiocarcinoma. Patients who experience a course that becomes rapidly progressive should be examined by endoscopic retrograde cholangiopancreatography (ERCP) with brushings to evaluate for cholangiocarcinoma. In addition to the usual considerations about the timing of transplantation, it is important to note that these patients are susceptible to bacterial cholangitis, which can cause systemic sepsis and rapid hepatic decompensation. Episodes of cholangitis that do not respond to suppressive antibiotic therapy should prompt early consideration for transplantation. Overall, patients with PBC or PSC experience the best outcomes with transplantation when compared to adults with other liver diseases, however, disease recurrence remains higher in PSC patients than in PBC patients.^{3,43}

Inherited Metabolic Disorders

Numerous inherited metabolic disorders are treatable by liver transplantation (Table 37-3). Some enzymatic deficiencies in this group result in destruction of the liver, so transplantation may resolve the liver failure as well as supply the missing enzyme. Disorders in this category include Wilson disease, alpha-1 antitrypsin deficiency, tyrosinemia, and type I glycogen storage disease. In other cases, the liver

is not affected by the disease, either structurally or functionally. In these circumstances transplantation is undertaken solely as enzyme replacement therapy. Diseases that have been cured by hepatic transplantation in this category include hemophilia A or B, homozygous familial hypercholesterolemia, Niemann–Pick disease, oxalosis, familial amyloid polyneuropathy, and numerous enzymatic deficiencies of urea cycle metabolism.⁴⁴ Determination of eligibility for transplantation depends on determining that transplantation will cure the disease, or at least halt its progression, and that the consequences of the disease without transplantation are devastating, making transplantation appropriate.

Budd–Chiari Syndrome

Budd–Chiari syndrome is characterized by obliteration of the hepatic veins. It may be due to congenital webs of the hepatic veins or suprahepatic cava or may be caused by spontaneous thrombosis of the hepatic veins. The latter condition is associated with polycythemia vera and other hypercoagulable states. Diagnosis is made by inferior vena cavagram or magnetic resonance venography. The classic presentation is a triad of right upper quadrant pain, hepatomegaly, and ascites. Patients may present with FHF during acute Budd–Chiari and have symptoms of encephalopathy and coagulopathy, or they may present in a more indolent fashion with ascites as the predominant feature. The natural history of the indolent form of Budd–Chiari syndrome is the eventual development of cirrhosis.

Patients who present with intact hepatic function should undergo an assessment to determine whether the liver has evidence of cirrhosis. A transjugular intrahepatic portosystemic shunt (TIPS) is the preferred therapy for patients who do not have evidence of synthetic failure and have not yet developed cirrhosis. Transplantation is reserved for cases where portal decompressive shunting is not possible or for patients who have advanced cirrhosis. Long-term anticoagulation to prevent recurrent hepatic vein thrombosis in the liver graft is routinely recommended.

Other Considerations

HPS and PPHTN are two other manifestations of cirrhosis whereby transplantation is justified. Similar to HCC, these two diseases can occur in cirrhosis despite overall preserved hepatic function and appear to involve dysregulation of vasoactive mediators such as nitric oxide. Therefore, MELD exception scores are often sought when either HPS or PPHTN are present.¹² HPS is diagnosed on the basis of unexplained hypoxia in the presence of cirrhosis along with a positive “bubble” study for pulmonary shunt on echocardiography. PPHTN is diagnosed on the basis of pulmonary hypertension in the setting of cirrhosis without any other explainable etiology such as underlying pulmonary pathology. Recipient selection and management is critical to achieve reasonable success with liver transplantation. Patients with HPS experience the best outcomes if preoperative PaO₂ is greater than 50 mm Hg.⁴⁵ Patients with PPHTN likewise must have mean pulmonary artery pressures less than 35 mm Hg with or without medical therapy to experience a reasonable chance of recovery following liver transplantation.^{46,47}

In addition to isolated liver disease, liver transplantation is occasionally considered along with other solid organ transplantation. The two most notable examples are combined kidney and liver transplantation as well as combined liver and intestine transplantation.⁴ Intestine transplantation is usually performed in cases where intestinal failure is present along with progressive cholestatic liver failure secondary to hyperalimentation.⁴⁸ Since HRS frequently occurs with advanced cirrhosis and also frequently resolves with successful liver transplantation, the indications for combined liver and kidney transplantation are more controversial.⁴⁹ It is widely accepted that pre-existing end-stage renal disease along with significant cirrhosis or the existence of HRS requiring eight or greater weeks of renal replacement therapy warrant consideration of combined liver and kidney transplantation. Ongoing investigations are required to define patients with HRS who are less likely to recover renal function following liver transplantation.

LIVER TRANSPLANTATION: SURGICAL PROCEDURE

Anesthetic Management

An anesthesiologist with experience in liver transplantation is invaluable to the transplant team and liver transplant anesthesiology is rapidly becoming a subspecialty. Proper anesthetic management and effective communication between the surgery and anesthesiology teams is necessary to optimize patient care during the surgical procedure. While an extensive outpatient preoperative evaluation is usually performed, including cardiac risk stratification, many liver candidates report from home when a liver

becomes available. If adequate time for fasting has not occurred, consideration of rapid sequence induction should be given to prevent aspiration. After induction and intubation, general anesthesia is maintained with a combination of inhalational agents as well as the administration of paralytic agents and analgesics. For adult patients, cardiac monitoring is often performed either by pulmonary artery catheterization or intraoperative transesophageal echocardiography. An arterial catheter is placed for blood pressure monitoring. Adequate vascular access, often including central venous catheters, is required for the administration of blood products and the potential for rapid resuscitation in the case of massive blood loss. A device for rapid infusion and the ability to warm blood products or intravenous fluids is required. Low central venous pressures maintained during the hepatectomy phase of the procedure may help avoid excess bleeding.

Intraoperative Management of Coagulopathy

Liver transplantation has the potential for massive blood loss for several reasons. Liver transplant candidates with cirrhosis often have synthetic deficiencies in circulating coagulation factors as well as severe portal hypertension associated with thrombocytopenia and extensive venous collaterals. Intraoperative coagulopathy may be worsened during the anhepatic phase of the procedure. Finally, liver transplantation involves extensive dissection of major vascular structures including the inferior vena cava, portal vein, and hepatic artery, all with an inherent risk for torrential bleeding.

Intraoperatively, coagulation is monitored by frequent determination of standard parameters including prothrombin time, partial thromboplastin time, platelet count, and fibrinogen. Abnormalities of these laboratory values associated with intraoperative bleeding are often corrected with fresh frozen plasma, platelets, or cryoprecipitate. Normal coagulation is also helped by maintaining normal pH, calcium levels, and normothermia. While the administration of recombinant factor VII intraoperatively can rapidly and effectively stop nonsurgical bleeding, its use has a theoretical risk of postoperative thrombotic complication including hepatic arterial thrombosis. In addition, no definitive data has been demonstrated to decrease the need for intraoperative blood transfusions.^{50,51} Therefore, its use is only recommended in emergent situations.

Following reperfusion of the donor liver, a fibrinolytic state may be encountered. This is related to the lack of production of fibrinolysis inhibitors during the anhepatic phase and the inability of the liver to metabolize profibrinolytic compounds. This state may be identified either by thromboelastography, recurrence of bleeding where hemostasis had been previously obtained (such as the wound edge), or by extensive and refractory bleeding after revascularization. This state may be treated with the use of antithrombolytic agents including ϵ -aminocaproic acid, tranexamic acid, or aprotinin.

Surgical Technique

Transplantation of the liver is among the most technically demanding surgical procedures. During induction and placement of the appropriate monitoring lines by the anesthesiology team, the donor liver is prepared on the back table for implantation (Fig. 37-4). Bench preparation includes resection of the donor diaphragm and adrenal gland off of the bare area of the liver and vena cava. Meticulous ligation of tributaries from the vena cava (adrenal vein, phrenic vein, and lumbar branches) is performed. The artery is dissected free from the Carrel patch of the aorta up to the gastroduodenal artery. Dissection near the right or left hepatic arteries is avoided to prevent unnecessary injury. The portal vein is circumferentially dissected free. The gallbladder may be removed at this stage or following reperfusion. Tissues surrounding the common bile duct are left intact to avoid injury of the blood supply.

Following this, the recipient's abdomen and bilateral groins are prepped and draped in a standard fashion. The most commonly used incision is a unilateral or bilateral subcostal incision with a midline extension to the xiphoid process (Fig. 37-4). After dividing the fascia, ascites, which can occasionally be present in a large volume, is evacuated. The ligamentum teres hepatis is carefully divided between clamps and ligated because a large recannulized umbilical vein is often present in patients with severe portal hypertension. After dividing the falciform ligament with cautery, a mechanical retractor is used to retract the bilateral costal margins anteriorly and superiorly for excellent exposure of the upper abdomen. The abdominal cavity and liver are then inspected for any abnormalities including unsuspected malignancy, particularly within the cirrhotic liver which is a risk factor for HCC. Following this, liver transplantation occurs in three stages: (1) recipient hepatectomy, (2) anhepatic phase, and (3) postrevascularization.

Recipient Hepatectomy

During the recipient hepatectomy phase, the liver is mobilized from its ligamentous attachments and the porta hepatis is skeletonized. Attention is first directed to dissecting and skeletonizing the structures of the portal triad. The peritoneum overlying the portal triad is divided with electrocautery near the liver edge. The right and left hepatic arteries are dissected free, ligated, and divided leaving adequate length to form a branch patch for the arterial anastomosis. The proper hepatic artery is also dissected free to the level of the gastroduodenal artery allowing enough length for clamping during the anastomosis. Because portal venous flow of blood to the liver may be hepatofugal (away from the liver), division of the artery may leave the patient functionally anhepatic. If a prolonged period of time is expected for mobilization of the liver, such as when extensive adhesions are present, the artery may be dissected free but left in continuity to allow whatever synthetic capacity the native liver has to continue. A replaced or accessory right hepatic artery, which arises as a branch of the superior mesenteric artery and travels in a posterior position to the common bile duct and lateral to the portal vein, can usually be palpated if present and can be ligated and divided. When the replaced right hepatic artery is relatively large and the proper hepatic artery is diminutive in size, the replaced right hepatic artery can be left long and used for arterial inflow for the donor liver. A replaced or accessory left hepatic artery arises from the left gastric artery if present and can be identified by inspection of the pars flaccida of the lesser omentum along the lesser curvature of the stomach (Fig. 37-5).

Figure 37-4. A: The donor liver after excision and before transplantation. B: Bilateral subcostal incision with a subxiphoid extension.

Figure 37-5. A replaced left hepatic artery usually arises as a branch of the left gastric artery, traversing the pars flaccida of the lesser omentum from left to right toward the left lobe of the liver.

Conceptually, the common bile duct and common hepatic duct should be dissected free with as much length as possible and without injuring the blood supply to the bile duct. Leaving the recipient bile duct as long as possible allows the length of the donor bile duct, which may have a tenuous blood supply, to be shorter and still avoid tension at the time of anastomosis. This is accomplished by first ligating and dividing the cystic duct. The common bile duct and common hepatic duct are then circumferentially dissected free leaving the surrounding tissue to preserve the bile duct blood supply. The common hepatic duct is then ligated as close to the native liver as possible.

Once the bile duct and the hepatic artery are freed from surrounding tissues, the portal vein can be easily approached from its anterior, medial, and lateral aspects. In general, the portal vein is freed circumferentially from the edge of the duodenum up to its bifurcation of the right and left portal veins. Small branches may arise near the pancreas and excessive bleeding may arise if these are inadvertently injured. Most patients with severe portal hypertension will not develop hypotension, small bowel edema, or ischemia if the portal vein is clamped and divided because of the presence of portal venous collaterals. However, patients without portal hypertension such as those undergoing liver transplantation for fulminant hepatic failure, metabolic deficiency, or those who have had a transjugular intrahepatic portosystemic shunt (TIPS) for a prolonged period of time, may develop extensive small bowel edema or hypotension when the portal vein is clamped. Small bowel edema can lead to limited exposure in the right upper quadrant making implantation of the liver extremely difficult. In these situations, the portal vein should be left in continuity for as long as possible, particularly when the use of venovenous bypass is not intended. For those patients with portal vein thrombosis, portal venous flow can be restored in most cases. Often, the thrombus can be evacuated with the use of forceps or by placing a Yankauer suction tip within the lumen of the portal vein. If the thrombus is more mature, an eversion endovenectomy may be necessary.⁵² If these maneuvers are unsuccessful, the junction of the splenic vein and superior mesenteric vein may be patent. Dissection of the portal vein behind the pancreas to this junction can then be performed to allow for future anastomosis. Dissection to the confluence of the splenic and superior mesenteric veins is sometimes necessary in pediatric recipients because of the small caliber of the portal vein within the porta hepatis. In rare cases, all of these maneuvers may be unsuccessful and a venous bypass graft from the superior mesenteric vein may be necessary. If the superior mesenteric vein is also occluded, the inferior vena cava or left renal vein can be used for portal inflow, a procedure termed cavoportal or renoportal transposition.⁵³ This procedure is associated with acceptable outcome despite the fact that portal hypertension may not be alleviated. A fourth option is arterialization of the portal vein, using a conduit created by anastomosing donor iliac vessels to the recipient aorta and connecting this to the donor portal vein.⁵⁴

The ligamentous attachments of the liver, including the left and right triangular and coronary ligaments are then divided using electrocautery. The bare area of the liver is dissected along a plane just superficial to the capsule of the liver. Care must be taken to avoid injury to the phrenic or hepatic veins when freeing the suprahepatic inferior vena cava where it traverses the diaphragm. The hepatocaval ligament along the right lateral aspect of the vena cava can be divided using a combination of cautery and ligation as a phrenic venous branch is often present within this ligament. The liver is then dissected off of the anterior aspect of the inferior vena cava. Small venous branches from the inferior vena cava to the caudate lobe are ligated and divided. Larger branches, such as an accessory right hepatic vein, are clamped, divided, and oversewn. Division of the portal vein facilitates exposure for this dissection but is not required. The liver may be gradually retracted and dissected from either the right or left aspects until the right, middle, and left hepatic veins are reached. If a bicaval venous anastomosis technique will be used, the vena cava can be circumferentially mobilized near the diaphragm above the hepatic veins as well as in an infrahepatic position. However, if a piggyback or cavocavostomy (side-to-side caval anastomosis) technique is intended; the dissection of the posterior aspect of the vena cava should be avoided to prevent encountering unnecessary bleeding from collateral or lumbar venous branches in this area.

Anhepatic Phase and Implantation of the Donor Liver

At this point, the liver has been completely mobilized except for its attachments of the hepatic veins to the inferior vena cava and in some cases, the portal vein. The decision should now be made whether to use venovenous bypass. Most patients will tolerate clamping of both the portal vein and the inferior vena cava without difficulty.⁵⁵ At this point, communication with the anesthesiologist is essential and the vena cava should be test clamped before division to make sure that adequate cardiac filling and blood pressure can be maintained. If the patient becomes hypotensive during test clamping, the clamp

should be removed and additional volume or pressor support can be administered. Occasionally patients will require venovenous bypass, but its use is no longer routine at most centers.

If necessary, venovenous bypass can be accomplished from both the portal vein and inferior vena cava simultaneously, or a single cannula in either the portal vein or the inferior vena cava may be used (Fig. 37-6). There are several accepted methods of placing cannulas for venovenal bypass. Cannulas may be placed percutaneously in the internal jugular vein and femoral vein prior to beginning the procedure. These cannulas are advanced into the superior and inferior vena cava, respectively. Alternatively, one or both of the bypass cannulas may be placed by cutdown on the axillary and/or the greater saphenous vein. Inferior vena caval and mesenteric blood is delivered to the superior vena cava by a centrifugal pump. The cannulas, tubing, and centrifugal pump head are heparin bonded to reduce the chance of thrombus formation and subsequent embolism without the use of anticoagulation. Flow rates of 1 to 2 L/min are usual.

Once venovenous bypass has been established or the decision to forego bypass has been made, the recipient hepatectomy is completed. If still intact, the portal vein is divided as high in the hilum as possible. Three methods are commonly used for orthotopic liver transplantation: (1) the bicaval technique, (2) the piggyback technique, (3) cavocavostomy (side-to-side caval technique).

1. For the bicaval technique, the recipient liver is excised en bloc with the retrohepatic inferior vena cava after caval clamps have been placed in a suprahepatic and infrahepatic position. The hepatic veins are divided within the substance of the liver to allow the creation of a large suprahepatic cuff compromising the left, middle, and right hepatic veins (Fig. 37-7). This technique has the disadvantages of: (a) totally obstructing inferior vena cava flow resulting in renal ischemia and decreased cardiac filling with associated hypotension possibly leading to the requirement of venovenous bypass, (b) requires two vena caval anastomoses prolonging the warm ischemic time, (c) requires dissection posterior to the vena cava possibly leading to bleeding. However, complete dissection of the caudate lobe off of the vena cava is not necessary making the recipient hepatectomy phase somewhat easier and faster.

Figure 37-6. Setup for venovenous bypass during hepatic transplantation. Cannulas are placed into the portal vein to decompress the splanchnic bed and inferior vena cava (through the greater saphenous vein) to decompress the lower extremities and kidneys

during the anhepatic phase of the transplantation. A centrifugal pump is used to deliver bypassed blood to the central circulation by means of a cannula passed into the axillary vein.

Figure 37-7. A: The diseased recipient liver is removed by incising the liver below the level of the hepatic veins. B: The hepatic veins are then opened to form a large suprahepatic cuff for anastomosis. The suprahepatic vena caval anastomosis: posterior suture line (C); anterior suture line (D).

2. For the piggyback technique, a clamp is placed transversely, partially occluding the vena cava at the level of the hepatic veins. The vena cava is left in continuity and the hepatic veins are divided within the substance of the liver allowing the creation of a common patch of the right, middle, and left hepatic veins for a wide anastomosis. While the intention is to only partially occlude the vena cava allowing venous return to the heart, often a clamp placed for the piggyback technique either occludes or nearly occludes the inferior vena cava. This technique does have the advantage of only requiring a single vena caval anastomosis helping to limit warm ischemic time. However, torsion may occur if the right upper quadrant is relatively large, such as when a large volume of ascites is present, and the donor right hepatic lobe is relatively small. This may lead to right hepatic vein or inferior vena caval stenosis.
3. For the cavocavostomy technique, clamps can be placed on the right hepatic vein as well as the junction of the left and middle hepatic veins. The liver is excised and these venous branches are oversewn and the clamps are removed. Alternatively, the hepatic veins can be divided using an Endo GIA stapler (Fig. 37-8). Advantages of the cavocavostomy anastomosis include: (a) minimalization of the time that the vena cava is clamped, (b) the vena caval clamp is placed longitudinally only

occluding the anterior third of the vena cava leading to minimal or no changes in the recipient's hemodynamics, (c) a cavoplasty is performed limiting the likelihood of caval stenosis, (d) a long anastomosis is performed, often over 6 cm in length, minimizing the risk for hepatic vein outflow complications, (e) exposure during suturing of the anastomosis is considerably improved compared to the piggyback or bicaval technique.

Figure 37-8. Cavocavostomy. **A:** The recipient right and junction of the middle and left hepatic veins are stapled and the inferior vena cava is left in continuity. **B:** The supra- and infrahepatic vena cavae are stapled and a venotomy is made longitudinally on the posterior aspect of the donor liver. **C:** A side-to-side caval anastomosis is performed with a running suture.

After removal of the recipient liver, the right upper quadrant is carefully inspected and hemostasis is obtained. Complete hemostasis in the bare area is essential at this time because this region is easily visualized when the liver is absent but may be relatively inaccessible once the donor liver is implanted, especially if the donor liver is relatively large or the recipient is obese. Argon beam coagulation can also be used to aid in hemostasis at this point.

The donor liver is then brought onto the operative field. The vascular anastomoses are performed using a running monofilament polypropylene suture. If a bicaval technique is planned, two caval anastomoses are required. The suprahepatic vena caval anastomosis is first performed by suturing the posterior walls from within the lumen using an imbricating technique (Fig. 37-7). The anterior wall is then completed. The infrahepatic anastomosis is then completed in a similar fashion. Redundancy in the donor vena cava is avoided to prevent the potential for kinking. The completion of the anastomosis may be left until the time of hepatic revascularization to provide a vent for air, acidotic or hyperkalemic blood, and for residual preservation solution. Venting of blood prior to reperfusion is most important if preservative solutions containing a high concentration of potassium, such as University of Wisconsin solution, were used. Venting of blood is less critical if preservative solutions that do not contain high concentrations of potassium are used, but care must still be taken to avoid the rapid bolus of air or cold blood to the heart. For the piggyback technique, the donor infrahepatic vena cava is either oversewn or stapled. The donor infrahepatic vena cava is then sewn in an end-to-side fashion to the recipient hepatic vein cuff (Fig. 37-9). As described above, an imbricating suture technique is often helpful to prevent gaps in the anastomosis and to compensate for size discrepancies. Venting at the time of reperfusion can either be performed through the suprahepatic anastomosis or at the donor infrahepatic vena cava. For the side-to-side caval technique, a clamp is placed longitudinally on the anterior third of the recipient vena cava. A longitudinal venotomy is made on the anterior surface of the recipient vena cava. The donor supra- and infrahepatic vena cavae are either oversewn or stapled closed. A longitudinal posterior venotomy was then made matching the length of the recipient venotomy. The liver then placed in the right upper quadrant in the left lateral segment is elevated. The two vena cavae are then sutured in a side-to-side fashion with the lateral wall sutured from within the lumen and the medial wall sutured from outside the lumen (Fig. 37-8). Venting can be performed from either the suprahepatic donor vena

cava or the medial wall of the anastomosis. During the caval anastomosis, the donor liver may be perfused with cold fluid via a cannula placed within the donor portal vein to wash out the preservation solution and to help maintain the cold temperature of the liver. This step is not required but may be considered if the liver was preserved with a solution containing a high concentration of potassium or if a prolonged warm ischemic time is anticipated.

Once the caval anastomosis or anastomoses are completed, either the portal anastomosis, arterial anastomosis, or both can be performed prior to reperfusion. In theory, reperfusion with arterial blood would limit the extent of warm ischemia to the biliary tree which, unlike the remainder of the liver, receives its blood supply exclusively from the arterial blood and not along with portal venous blood. However, neither sequence has been clearly shown to be an advantage over the other, so the choice is made based on the surgeon's preference and the patient's anatomy. Most commonly, the portal venous anastomosis is completed and the liver is reperfusion. If portal bypass has been used, the portal limb of the venovenous bypass circuit is removed. The portal anastomosis is usually performed in an end-to-end fashion using a running technique. To avoid narrowing and allow for expansion under venous flow, an air knot is used when the suture is tied.

Figure 37-9. A: Recipient liver is dissected off native inferior vena cava by dividing veins draining directly into the inferior vena cava up to the level of the hepatic veins. B: Clamp placed on recipient hepatic veins in preparation of excision of the recipient's native liver and performance of a piggyback anastomosis.

At the time of revascularization, flow is restored to the liver through the portal vein and/or the hepatic artery. The first several hundred cc of blood may be vented through the infrahepatic vena cava and the knot can be tied completing the caval anastomosis. Alternatively, the caval clamp can be briefly opened and the anastomosis inspected for bleeding and, repaired if present. If blood is not vented through the infrahepatic cava, portal blood should be restored gradually to minimize cardiac irritability, bradycardia, and hypotension, all of which routinely result from cold blood circulating through the donor liver and going directly into the right atrium. Close coordination between the surgeon and anesthesiologist is necessary during this phase as hypotension and bradycardia are routinely encountered and cardiac arrest may rarely occur. If venovenous bypass has been used during the anhepatic phase, it can now be discontinued.

Once hemostasis is obtained and the patient has stabilized, attention can now be turned toward the arterial anastomosis if it has not already been performed. Conceptually, the arterial anastomosis can be performed in one of two ways. The anastomosis can be performed with the artery being very long, which allows the artery to lie with a smooth and gentle curve or loop (Fig. 37-10). For this technique, all branches on the donor artery are ligated and the donor aortic Carrel patch, celiac artery, or branch patch of the celiac and splenic artery are anastomosed in an end-to-end fashion to a branch patch of the recipient right and left hepatic arteries (Fig. 37-11). Alternatively, the artery can be cut to just the right length and sewn in an end-to-end fashion. This is often performed by forming branch patches between the donor gastroduodenal and recipient proper hepatic arteries and performing the anastomosis in an end-to-end fashion. However, when the retractor is released, the liver may shift position and kinking of the artery may occur. Therefore, judging the proper length of the arteries may be difficult and this technique may be more technically demanding than the method which leaves the artery very long. If

the artery is somewhat long but not long enough to allow a gentle or smooth curve or loop, kinking and obstruction to blood flow may occur. For both techniques, the anastomosis can be performed using a fine, nonabsorbable, monofilament, running suture. If the recipient arterial inflow is inadequate, an aortic conduit may be constructed. This is often performed using a graft consisting of the donor common and external (or internal) iliac artery. A partially occluding aortic clamp can either be placed in a supraceliac or infrarenal position and the common iliac artery is sutured in an end-to-side fashion to the recipient aorta. The donor Carrel patch can then be sutured in an end-to-end fashion to the external iliac artery of the conduit.

Figure 37-11. A: The donor hepatic artery is procured with a Carrel patch of aorta. B: The recipient hepatic artery bifurcation is used to fashion a branch patch for a larger anastomosis. C: The anastomosis is carried out using continuous monofilament suture material. D: The completed anastomosis.

Postrevascularization Phase

Following revascularization, the liver should assume a normal color and consistency within several minutes. If the liver remains pale or is overly soft, problems with portal inflow should be considered. Alternatively, if the liver becomes edematous and overly firm, outflow obstruction should be excluded. Bile production should be seen while in the operating room and is among the first evidence for liver function. In contrast, watery or milky fluid from the bile duct raises concern for primary nonfunction. Inspection for surgical bleeding should be performed and entails examination of the vascular anastomoses as well as a search for branches of the major vessels that may not have been ligated. If bleeding continues after all surgical bleeding has been resolved, attention should be directed toward correction of coagulopathy as described above.

While biliary reconstruction does not carry the same risk for intraoperative complications when compared to the recipient hepatectomy and reperfusion, it is associated with considerable postoperative morbidity and mortality and requires the same diligence and attention as other step of the operation. Because of the relatively high complication rate associated with biliary reconstruction, it has been referred to as the Achilles heel of liver transplantation. There are several options for biliary reconstruction. In the past, the Calne conduit, or the use of the donor gallbladder, was used but has been abandoned due to the high rate of biliary complications associated with it. The simplest and most common technique is currently an end-to-end choledochocholedochostomy from the donor to the recipient bile duct (Fig. 37-12). If a size discrepancy exists, the narrower duct can be spatulated. Running or interrupted sutures can be used. Absorbable monofilament suture is most commonly used to avoid a nidus for future stone formation within the bile duct. While T. tubes were commonly used in the past to stent the anastomosis, evidence now shows that more leaks or strictures develop as a result of the T tube than are prevented. Internal biliary stents may be used and may help prevent leaks or strictures.⁵⁶ Alternative biliary reconstruction methods may be necessary for those with a bile duct of inadequate quality or size or in those whose primary disease is biliary pathology such as PSC or biliary atresia. The most common option employed in these situations includes a standard Roux-en-Y choledochojejunostomy. If a prior choledochojejunostomy had been performed in the past, the limb of small bowel used may often be salvaged and used for biliary drainage of the new liver. Placement of drains is optional but may help identify and treat biliary leaks. Abdominal wall and skin closure is then performed in the standard fashion.

Technique for Reduced Size and Split Liver Transplantation

In the 1980s, the waiting list mortality for small, pediatric liver candidates was relatively high because the number of suitably sized small liver donors was inadequate. As a result, techniques to reduce the size of an adult liver, based on Couinaud segmental anatomy (Fig. 37-13), were developed so that the left lobe, left lateral segment, or even a single segment could be used for a recipient more than 10 times smaller by weight than the donor.^{57,58} During the early experience, the donor hepatectomy was performed in a standard fashion and the liver was brought back to the recipient hospital. The needed segments of the liver were cut down on the back table with the organ on ice, the vessels were left intact to the future transplant graft, and the remainder of the liver was discarded. Techniques have now developed so that both sides of the liver can be transplanted into two recipients, either a child and an adult or two adults.^{59,60} In addition, the liver may be split in situ at the donor hospital, allowing coagulation of the cut edge of the liver so that bleeding is minimized following reperfusion. Perfusion to both sides of the liver can be inspected prior to flushing ensuring that blood flow to all segments of each future graft has been preserved. Because of technical and practical issues, both the cut down technique and in situ splitting of the liver are still employed. Split liver transplantation has been associated with a decreased survival rate and the potential for increased risk of complications, including primary nonfunction, hepatic artery thrombosis, and biliary complications. Because of this, while widespread adoption of allocation policies to encourage greater utilization of split liver grafts in the adult population has been suggested, split liver transplantation only accounts for a small proportion of transplants performed. In addition, only grafts from “ideal donors” are thought to be suitable to this form of transplantation. Criteria supported by the UNOS for splitting currently include donor age less than 40 years of age, on a single or no pressors, transaminases no greater than three times normal, and a body mass index of 28 or less.

Figure 37-12. A: In most cases, a choledochocholedochostomy is performed, possibly over an internal stent. B: Patients with a diseased or unsuitable common bile duct may require biliary reconstruction with a Roux-en-Y choledochoenterostomy.

Living Donor Liver Transplantation

Experiences with deceased donor split liver transplantation as well as the success with living donor kidney transplantation led to the adoption of the techniques for split liver transplantation to living donor liver transplantation. The first living donor liver transplantation allowed an adult volunteer to donate the left lateral segment of the liver to a child. Based on the success of living donation in the pediatric population as well as the increased waiting list mortality rate for adults, these techniques have also been applied to adult recipients receiving either the right or left lobe from an adult volunteer.⁶¹ Living donor liver transplantation was progressively developing in the United States until a well-publicized donor mortality occurred.⁶² Living donor liver transplantation now accounts for approximately 5% of all liver transplants performed in the United States. In Japan and other areas of the Far East, where deceased donor transplantation has developed slower because of cultural difficulties with the concept of brain death, living donor transplant are the rule rather than the exception.

Figure 37-13. Segmental anatomy of the liver as based on Couinaud nomenclature.

Figure 37-14. Living donor right hepatic lobe allograft demonstrating the right hepatic vein (RHV), right portal vein (RPV), right hepatic artery (RHA), and two right hepatic ducts.

In many respects, transplantation of a graft from a living donor is similar to transplantation of a whole liver from a deceased donor. However, a bicaval technique is not possible given that the donor vena cava is not available for replacement of the recipient's retrohepatic inferior vena cava (Fig. 37-14). Therefore, the recipient vena cava must be left intact. A direct hepatic vein to vena caval anastomosis is used (Figs. 37-15 and 37-16). Establishing adequate outflow of hepatic venous blood is necessary to help prevent edema of inadequately drained segments of the liver possibly leading to small-for-size syndrome. Therefore, any accessory veins greater than 5 mm in diameter should be reconstructed either by direct anastomosis to the vena cava or using an interposition graft. In addition, the length of the portal vein, hepatic artery, and bile duct on the donor graft is considerably shorter than that available from a deceased donor. Therefore, during the recipient hepatectomy, considerable care should be given to preserving the length of the recipient bile duct as well as the right and/or left hepatic artery and portal vein which are intended for future anastomosis.

Figure 37-16. Right lobe (segments V to VIII) living donor transplantation. **A:** Donor operation. **B:** Recipient operation completed.

Auxiliary Liver Transplantation

Under select circumstances, there is a good rationale for placing the donor allograft in a heterotopic rather than orthotopic position, leaving the native liver in place. This procedure is known as auxiliary liver transplantation. Auxiliary liver transplantation has occasionally been used for cases in which liver transplantation is indicated for somatic genetic deficiency but the native liver is otherwise normal in all other respects. It is also been used in cases of FHF where the liver candidate is expected to die in the near future without transplant but if adequate time was allowed, the native liver may recover and return to normal. In this situation, immunosuppression can slowly be weaned, the transplanted liver will atrophy, and the recipient can be taken off of all immunosuppression. [Figure 37-17](#) demonstrates one technique used. Another option, auxiliary partial orthotopic liver transplantation (APOLT) has been developed. For this technique, part of the native liver is resected, often the right trisegment, leaving only the left lateral segment intact. The donor liver is then transplanted in an orthotopic position. If the native left lateral segment recovers, immunosuppression can be weaned leading to hypertrophy of the left lateral segment and involution of the allograft.

Complications

3 The degree of preoperative debilitation and the complexity of the operative procedure make complications following liver transplantation very common. Prompt recognition and treatment are essential. However, the usual signs or symptoms that would be expected in the general population are often absent or present to a lesser degree, and therefore, a high level of suspicion must be maintained. Early warnings, such as fever, leukocytosis, or pain may be suppressed as a result of immunosuppression. In addition, the burden of immunosuppression predisposes to additional problems not usually encountered in other areas of surgery. Complications associated with immunosuppression, which are predominantly infectious, are detailed in another chapter. In the following sections, some of the major surgical complications that occur after liver transplantation are described.

Primary Nonfunction

4 About 2% to 4% of transplanted livers function so poorly in the immediate postoperative period, from an unknown etiology that death is likely in the absence of retransplantation and is referred to as primary nonfunction. Most cases of primary nonfunction likely occur as a result of ischemic injury, occurring either in the donor or the recipient,⁶³ or from poor preservation. Donor factors known to predispose to primary nonfunction include allograft steatosis, advanced donor age, and prolonged cold ischemic time. In addition, donor race and the need for portal vein reconstruction have also been demonstrated to be risk factors for primary nonfunction.⁶⁴

Early evidence for primary nonfunction include poor bile production of the liver intraoperatively, refractory acidosis, progressive coagulopathy, and hepatic encephalopathy. In a short period of time, these early signs are often followed by acute renal insufficiency and eventually cardiopulmonary collapse. Serial factor V levels may be helpful to determine if a liver allograft is functioning in a patient who has received a massive transfusion of fresh frozen plasma. In this setting, the INR may reflect transfused coagulation factors rather than factors synthesized by the liver graft. Fresh frozen plasma contains relatively little factor V because this factor is relatively unstable in cold storage. Therefore, a steady increase in the factor V level suggests production by the liver rather than transfusion with fresh frozen plasma.

Liver transplant recipients in the United States with primary nonfunction, currently defined as those who were transplanted within 7 days and are anhepatic developed an AST above 3,000 along with either an INR above 2.5 and/or an acidosis, can be relisted as a status 1A. Patients listed as a status 1A receive regional priority over less ill patients and frequently wait only a period of few days for an appropriate donor to become available. Despite this preferential listing for retransplantation, primary nonfunction is associated with a mortality rate of more than 50%.⁶⁴

Postoperative Hemorrhage

Postoperative hemorrhage requiring laparotomy occurs in approximately 5% to 15% of liver transplant recipients. Postoperative bleeding should be suspected in any liver recipient during the immediate posttransplant period that develops tachycardia, volume-dependent hypotension, oliguria, and abdominal distention. Because many liver transplant recipients may have had a large volume of ascites preoperatively (sometimes more than 10 to 20 L), a considerable amount of bleeding may occur before developing an abdominal compartment syndrome. In general, attempts to correct coagulopathy should be made and reexploration should occur in patients with refractory hypotension, abdominal compartment syndrome, or ongoing need for blood transfusion. At exploration, a specific bleeding point often cannot be identified, suggesting that bleeding may be related more to coagulopathy than failure of surgical hemostasis. Therefore, waiting until coagulopathy is corrected before reexploration may be wise assuming that the recipient is otherwise reasonably stable.

Figure 37-17. Heterotopic auxiliary liver transplantation using a reduced-size allograft.

Hepatic Artery Thrombosis

The incidence of hepatic artery thrombosis ranges from 1% to 2% up to 10% in some populations. The incidence of hepatic artery thrombosis is higher in pediatric recipients as well as recipients of living donors or split livers. Other risk factors include receiving a liver from a donor who is significantly smaller than the recipient, the need for reconstructive arterioplasty in the presence of nonstandard donor anatomy, acute rejection within the first week posttransplant, placement of cytomegalovirus (CMV)-positive organs into CMV-negative recipients, and a recipient history of smoking.⁶⁵ The association between rejection and hepatic artery thrombosis may be the result of a decrease in hepatic

arterial flow that occurs when the liver is swollen and edematous or to release procoagulants into the microcirculation in association with the inflammatory injury of graft rejection.

Hepatic artery thrombosis can occur in the early, arbitrarily defined as within 30 days, or late posttransplant periods. Early hepatic artery thrombosis is usually identified within the first 10 days posttransplant. The diagnosis is suspected in the setting of unexpectedly high liver enzymes, an elevation in liver enzymes rather than a gradual decline, or poor synthetic function during the first week to 10 days posttransplant. Other signs of biliary ischemia from hepatic arterial thrombosis include the development of biliary leaks, strictures, or intrahepatic abscesses. Doppler ultrasonography is usually used to confirm flow within the extrahepatic and intrahepatic arteries. If inappropriate waveforms or no flow is identified, the diagnosis can be confirmed by angiography or reexploration. At exploration, flow can be restored within the hepatic artery approximately 80% of the time if the diagnosis is made early. However, despite restoring arterial flow, many of these recipients will still develop biliary complications.

Hepatic artery thrombosis that occurs months to years following liver transplantation does not always lead to graft failure. Although some patients develop biliary strictures and/or hepatic abscesses, approximately a third of patients do well without intervention.⁶⁶

The arterial blood flow in the reconstructed hepatic artery is an important determinant of long-term patency. It is believed that children are predisposed to hepatic artery thrombosis because they have smaller vessels and lower mean arterial blood pressure than adults. Pediatric patients with an arterial diameter of less than 3 mm have the highest incidence of hepatic artery thrombosis. However, the experience with pediatric living donor transplantation, where very small arteries are routinely encountered, has indicated that with microsurgical technique it is possible to achieve a low hepatic artery thrombosis rate.⁶⁷

A postoperative hypercoagulable state associated with hepatic transplantation may predispose to hepatic artery thrombosis. Relatively poor hepatic production of natural regulatory anticoagulants, such as proteins C and S and antithrombin III, immediately after transplantation promotes coagulation because production of procoagulant factors, such as factor V and VII, occurs more rapidly after revascularization.⁶⁸ This observation has prompted some centers to administer fresh frozen plasma as a source of antithrombin III and proteins C and S in the postoperative period. Most centers recommend prophylactic aspirin to prevent hepatic artery thrombosis in children.

Portal Vein Thrombosis

Postoperative portal vein thrombosis is much less common than hepatic artery thrombosis, occurring in 1% to 3% of cases. A higher incidence of portal vein problems is seen in patients that have had previous portal vein operations or prior thrombosis of the portal system. Factors that decrease antegrade portal flow also predispose to portal vein thrombosis. Patients with chronic portal hypertension often spontaneously develop large retroperitoneal collaterals from the portal venous system to the renal vein and inferior vena cava. A previous surgically created splenorenal shunt should be disconnected at the time of transplantation because it usually is associated with reduced flow through the portal vein. This can be accomplished easily during a liver transplant by dissecting down the vena cava and ligating the left renal vein at its origin. This maneuver does not compromise the function of the left kidney. This maneuver can also be useful to improve portal flow if preoperative imaging discloses large spontaneous portosystemic shunts to the left renal vein.

Portal vein thrombosis should be suspected when the recipient develops symptoms of portal hypertension or ascites that is unusually difficult to control. Doppler ultrasound examination is usually the first diagnostic tool, but magnetic resonance imaging is also an option, as are standard mesenteric arteriography with portal phase views and direct percutaneous transhepatic portography. Transhepatic portography is particularly useful if a stenosis, rather than thrombosis, is identified because it is possible to both measure the pressure gradient across a stenotic area and treat a stenotic area with angioplasty and/or stent placement.

When portal vein thrombosis is identified in the immediate postoperative period, reexploration and attempted thrombectomy are usually indicated. Thrombectomy is more likely to be successful if a technical flaw in the anastomosis is present and can be corrected. When performing thrombectomy, it is advisable to avoid using balloon embolectomy catheters to remove clot from the mesenteric venous system, because these veins are very fragile and rupture of mesenteric veins deep in the mesentery can be catastrophic.

Hepatic Vein or Inferior Vena Cava Stenosis

Thrombosis of the inferior vena cava is a rare complication after liver transplantation, but hepatic vein outflow obstruction occurs in 2% to 4% of patients. Restrictions of hepatic blood flow may result from kinking of the suprahepatic cava. This is particularly problematic when the donor is small relative to the recipient and when the suprahepatic anastomosis is left long. Hepatic outflow problems can present with ascites and renal dysfunction. Presentation may be early in the first week after transplantation or months later. The diagnosis may be suspected on the basis of Doppler ultrasonography, but definitive diagnosis usually requires inferior cavography with measurement of pressure gradients. The incidence of caval complications utilizing the piggyback technique appears to be higher than the incidence with the bicaval technique, at approximately 4%.⁶⁹ Outflow stenosis appears to be more common if the combined orifice of two, rather than three, hepatic veins is used for the anastomotic site on the recipient when the piggyback technique is used. In many cases, hepatic vein or suprahepatic caval stenosis can be successfully treated noninvasively with the use of balloon angioplasty and stenting.^{70,71}

Biliary Leak or Stricture

Biliary leak or obstruction is a common surgical complication encountered after hepatic transplantation with an incidence of approximately 10% to 30%.^{56,72} Most biliary complications probably relate to ischemia of the donor biliary tree (Fig. 37-18). The transected donor bile duct is totally dependent on arterial flow from the liver graft. Therefore, when a biliary leak is identified, it is appropriate to interrogate the hepatic vasculature to rule out the presence of hepatic artery stenosis or thrombosis.

Although anastomotic biliary complications can result in mortality from sepsis, these most commonly lead to short-term morbidity. The initial management of biliary complications can generally be nonoperative. In most cases, the problem can be both diagnosed and treated by ERCP. If the biliary reconstruction was made using a Roux-en-Y hepaticojejunostomy, or if ERCP is unsuccessful, biliary leaks can be diagnosed and treated by interventional radiology using percutaneous transhepatic cholangiography and percutaneous placement of a biliary stent. In addition to stenting the anastomosis, it may be necessary to place a percutaneous drain if there is a significant extrahepatic collection of bile. In cases where initial studies show a large defect and in cases where the leak is not controlled through percutaneous measures, operative revision may be indicated.

Figure 37-18. Bile leak (arrow) from the choledochocholedochostomy after hepatic transplantation.

Biliary obstruction resulting from anastomotic strictures can also generally be managed nonoperatively by using percutaneous cholangioplasty or ERCP. When anastomotic strictures persist beyond two attempts at balloon dilatation and stent replacement, operative repair may be an option as long as the entire biliary stricture is extrahepatic and there are no intrahepatic strictures.

While anastomotic strictures are less likely to cause long-term morbidity, intrahepatic biliary strictures, also referred to as intrahepatic cholangiopathy, can be progressive and lead to allograft dysfunction, cholangitis, and ultimately to either death or retransplantation. Intrahepatic cholangiopathy is largely related to ischemic injuries and occurs in the setting of hepatic artery thrombosis and occurs in approximately 20% of donation following cardiac death (DCD) liver recipients.

Intra-Abdominal Sepsis

Intra-abdominal sepsis presents as diffuse peritonitis or localized abscess and occurs in about 5% of

patients who undergo liver transplantation. The most common cause of peritonitis is leakage of the biliary anastomosis. Abscesses may also develop spontaneously in the right upper quadrant or elsewhere in the abdomen. Most isolated infected fluid collections can be managed by percutaneous placement of drains guided by ultrasound or CT scanning, along with broad-spectrum intravenous antibiotics. Generalized infected ascitic fluid is managed with paracentesis and antibiotics. Surgical drainage may be necessary if leakage of enteric contents is suspected based on the finding of extravasated oral contrast in the peritoneal cavity on CT scan, or if the patient does not respond to percutaneous drainage.

Neurologic Complications

A number of preoperative and postoperative factors predispose to impaired consciousness and seizure activity after transplantation. Patients who have significant preoperative encephalopathy are more likely to suffer from postoperative neurologic symptoms. In the extreme, patients who are in hepatic coma from fulminant liver failure can sometimes take weeks to regain complete consciousness. Patients undergoing liver transplants are also at risk for watershed cerebral infarcts if significant intraoperative hypotension occurs. The effects of transient cerebral ischemia are worsened by the large amount of intravenous fluids that are often necessary during and after transplantation, which can exacerbate cerebral edema. Air embolism is also a risk if venous bleeding occurs from the inferior vena cava or hepatic veins at a time when the patient is relatively hypovolemic. If the patient has a patent foramen ovale, air embolism can result in cerebral ischemia if large bubbles lodge in the cerebral circulation. If the patient fails to awaken promptly after transplantation, and particularly if the transplant is functioning well, an urgent CT scan of the head should be obtained to rule out intracranial hemorrhage and to assess the degree of cerebral edema.

Seizures are reasonably common after transplantation. The calcineurin inhibitors cyclosporine and tacrolimus both lower seizure threshold and are associated with seizures following liver transplantation. Patients with a history of seizures are particularly predisposed to postoperative seizure activity. Seizures are treated with benzodiazepines acutely. Many long-term anticonvulsants alter the metabolism of calcineurin inhibitors. Therefore, levetiracetam is often used in substitution for these other anticonvulsants. To prevent recurrence of seizure activity it is usually necessary to decrease the dosage of calcineurin inhibitor to a lower target blood level. Frequently it is also necessary to change to a different calcineurin inhibitor altogether, or even to change the patient's maintenance immunosuppression to a regimen that does not include a calcineurin inhibitor.

REJECTION AND IMMUNOSUPPRESSION

5 For reasons that are not understood, liver transplant recipients require less immune suppression than patients with other types of allografts, such as heart, lung, and kidney recipients. This is somewhat surprising given that the mass of the liver is so great compared with the mass of the other organs. With current immunosuppressive therapy, graft loss from rejection is rare.

Antibody-Mediated Rejection

The liver is relatively resistant to injury from recipient antibodies, regardless of whether they are present at the time of transplant or develop later. This is very different compared with renal and cardiac recipients who experience rapid graft destruction, termed *hyperacute rejection*, if performed in a patient who has complement-fixing antibodies directed against the donor organ in significant concentrations at the time of transplantation. Hepatic graft injury from pre-existing antibodies directed at donor ABO determinants does occur, but in a much less pronounced fashion than in the context of renal transplantation. The overall results of ABO-incompatible liver transplants are somewhat inferior to those of ABO-compatible transplantations, but only by about a 10% to 20% decrease in 1-year graft survival rates compared to ABO-compatible grafts. Some of this decrease in graft survival rate may be due to the fact that ABO-incompatible transplants are usually performed only in dire circumstances where the patient is so ill that he or she may not survive the wait for a compatible organ. Because preformed antibodies do not seem to be clinically important, most transplantation programs do not perform prospective cross-matches between recipient serum and donor cells before transplantation, and determination of recipient and donor HLA type is no longer considered mandatory.

Why the liver is less susceptible to antibody-mediated destruction than the kidney is not clearly understood. One factor may be the vastly different microcirculation that the liver has compared with

the kidney, with a preponderance of sinusoidal channels and a smaller capillary network. It is probable that antibody-mediated injury affects blood flow through the delicate capillary network of the kidney more than it does to the liver sinusoids. In addition, each hepatocyte is exposed to two sinusoidal channels, presumably permitting survival if only one sinusoid is occluded. Finally, differences in HLA antigen expression are known to exist in the two organs, with the kidney the more antigenic of the two.

Cell-Mediated Rejection

6 Typical acute rejection in liver transplant recipients is usually cell mediated and occurs frequently but is effectively blunted by antirejection therapy. Acute rejection occurs most commonly in the first two postoperative months. In modern practice, cell-mediated rejection is a less common cause of graft loss than are primary nonfunction or hepatic artery thrombosis. Still, the effectiveness of antirejection treatment assumes a relatively early diagnosis and treatment of acute rejection, which is in turn the result of careful monitoring by the transplantation physician and compliance by the patient with frequent laboratory testing. Treatment of acute rejection with enhanced immunosuppressive therapy is highly effective, and an episode of rejection does not affect long-term graft survival. This is very different from renal transplantation, where an episode of rejection decreases long-term graft survival markedly.

The diagnosis of cell-mediated rejection is made primarily on a histologic basis. Clinical features can include low-grade fever and malaise, but frequently the patient is completely asymptomatic. Laboratory evaluation of peripheral blood may demonstrate leukocytosis and occasionally eosinophilia. Biochemical changes associated with rejection include elevated and rising levels of serum transaminases and alkaline phosphatase. A prolonged serum prothrombin time and an abnormal serum bilirubin also suggest the possibility of rejection, but frequently these parameters are normal if rejection is detected early. Any of these findings should prompt a biopsy.

Figure 37-19. Acute rejection of a liver transplant. **A:** A portal tract is expanded by a polymorphous inflammatory infiltrate consisting of large and small lymphocytes, plasma cells, macrophages, and neutrophils. The bile ducts (*arrows*) are damaged and inflamed. **B:** A central vein from the same biopsy exhibits endothelialitis, characterized by swollen endothelial cells and infiltrating lymphocytes. (From Thung SN, Gerber MA. Histopathology of liver transplantation. In: Fabry TL, Klion FM, eds. *Guide to Liver Transplantation*. New York: Igaku-Shoin Medical Publishers; 1988.)

The diagnosis of cell-mediated rejection rests on the finding of a triad of portal lymphocytosis, endotheliitis (subendothelial deposits of mononuclear cells), and bile duct infiltration and damage (Figs. 37-19 and 37-20). Various classification schemes have been devised to grade the severity of the rejection process based on the degree of cellular involvement or injury in these areas. Cell characterization studies have documented that the cells in the portal triads are primarily T cells, with fewer macrophages and neutrophils. Bile duct epithelial cells appear to be a prime target of immune attack, and they are known to express large amounts of class II HLA antigen.

If the recipient has hepatitis C, it is critical that recurrent hepatitis C is differentiated from acute rejection. At times the difference can be subtle, and a pathologist with experience in the interpretation of allograft biopsies is extremely valuable. Enhanced immunosuppression is associated with accelerated rates of hepatitis C viral replication; it is, therefore, important that immunosuppression is kept to a minimum for these patients.

Chronic Rejection

7 Chronic rejection is characterized by relentless immune attack on small bile ducts. Clinically, the pattern is one of gradual elevation of alkaline phosphatase and bilirubin, in the absence of obstruction of the large bile ducts. Histologically, small bile ducts are obliterated or completely absent, with a less pronounced cellular infiltrate than is seen with acute rejection. This finding has been termed *vanishing bile duct syndrome* when bile ducts are absent in 15 of 20 portal triads examined.⁷³ The loss of small bile ducts is partly the result of lymphocyte-directed attack on biliary epithelium. Relative to other cells in the liver, biliary epithelium tends to express more class I antigen. Thus, biliary epithelial cells are vulnerable targets for host attack because of their antigenicity. Loss of bile ducts may also occur indirectly as the result of ischemia secondary to immune-mediated obliteration of small to medium arteries. As in the case of renal transplantations, there is no effective treatment for chronic rejection except retransplantation.

Immunosuppression Induction and Maintenance

Multiple immunosuppressive protocols achieve acceptable suppression of allograft rejection for liver transplant recipients. Induction with antithymocyte globulin is no longer considered to be mandatory but is used at some centers. Similarly prednisone therapy, once considered a mainstay of a successful immunosuppressive protocol, is no longer considered absolutely necessary and when used is often tapered off rapidly. Treatment with a calcineurin inhibitor, either cyclosporine or tacrolimus is still considered to be imperative for most liver transplant recipients. These agents are associated with significant long-term morbidity, particularly the development of chronic renal failure. Dosages of these agents have gradually been reduced both to prevent renal insufficiency and to avoid the rapid and aggressive recurrence of hepatitis C infection. Induction antibody therapy with either polyclonal antilymphocyte preparations or with inhibitors of the receptor for IL-2 are still used commonly in the perioperative setting to avoid the nephrotoxicity associated with the immediate use of calcineurin inhibitors.

Figure 37-20. Arterial lesion of chronic hepatic rejection. Subintimal foam cells, intimal sclerosis, and myointimal hyperplasia obliterate the arterial lumen. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1999.)

Because immunosuppression predisposes to infection, prophylactic anti-infective drugs are usually administered. Trimethoprim–sulfamethoxazole, dapsone, or pentamidine is recommended to prevent *Pneumocystis carinii* infection. Oral Mycostatin or fluconazole therapy is used to prevent fungal infections, particularly esophageal *Candida albicans*. Either ganciclovir or valganciclovir is prescribed for patients who are at risk for CMV infection, which includes any patient exposed to CMV in the past and any patient transplanted with organs from a donor who has been exposed to CMV. Patients who are CMV negative who receive CMV-negative organs are not at high risk for CMV infection but should still receive prophylaxis against disseminated herpes simplex infections with acyclovir therapy. The duration of prophylactic anti-infective therapy has not been rigorously defined by evidenced-based trials and is therefore dependent on each center's experience with the prevalence of these infections in its patient population.

Treatment of Acute Rejection

Despite the overall effectiveness of the regimen described, acute rejection does occur and must be treated promptly. Several options are available for treatment of acute rejection, depending on the clinical circumstances. Traditionally, high doses of methylprednisolone are administered (usually 500

mg to 1 g) intravenously on a daily basis for 3 days. This treatment is effective in reversing most acute rejection episodes. Alternatively, increased doses of oral prednisone, a calcineurin inhibitor, or the addition of an antimetabolite drug, such as mycophenolate mofetil, will also reverse most episodes of rejection, particularly if the rejection is mild. Rejection that is resistant to these maneuvers or severe is treated with antilymphocyte therapy, either a monoclonal antibody directed at the T3 determinant common to all mature T cells (Orthoclone, OKT3) or polyclonal antilymphocyte treatments such as Atgam or Thymoglobulin. These treatments are typically administered daily for 5 to 10 days. These agents are highly effective, and it is unusual to lose an allograft secondary to acute rejection. However, these treatments are associated with profound and long-lasting immunosuppression, and it is usually advisable to restart prophylactic anti-infective therapies when they are initiated.

RESULTS

8 The patient survival rate following liver transplantation in the United States at 1 year is more than 85% for adults and nearly 90% for children. Patients who survive the first year following a liver transplantation experience approximately a 3% annual mortality rate thereafter, so 3-year survival rates for adults and children are currently 78% and 83%, respectively.

The most important predictors of survival following liver transplantation are whether the patient has previously undergone transplantation and whether the patient was in the intensive care unit at the time of transplantation. Although not as important as the condition of the patient at transplantation, the cause of liver failure is also an important determinant of success. Five-year survival varies from approximately 60% for patients transplanted for malignancy to 70% for patients transplanted for viral and alcoholic cirrhosis. The best 5-year survival rates of around 80% are seen with patients transplanted for metabolic liver disease, biliary atresia, and cholestatic liver diseases (PBC and PSC).³⁷ The volume of liver transplants performed at a given transplant center is also associated with patient survival, with higher-volume programs exhibiting higher adjusted overall patient survival rates.⁷⁴

Chapter 38

Cardiac Transplantation

Richard N. Pierson III

Key Points

- 1 Over the past 50 years, heart transplantation has evolved from public spectacle to accepted therapeutic modality based on improved tools to diagnose rejection and infection and an expanded armamentarium of treatment options.
 - 2 Heart transplantation is offered to patients who are at higher risk of death without transplant than with it, and for whom no other reasonable treatment options exist, while excluding those whose comorbid conditions are likely to significantly limit length or quality of life.
 - 3 The mortality rate for patients awaiting transplant has improved significantly over recent decades due to improvements in (a) patient selection, (b) medical therapy of patients awaiting transplantation, (c) mechanical support as a bridge to transplant, and (d) donor management and allocation algorithms.
 - 4 Of the four techniques for performing heart transplantation, orthotopic transplant using bicaval right atrial connections has emerged as the most popular.
 - 5 A “triple-drug” regimen including a calcineurin inhibitor, an antimetabolic agent, and a steroid, with or without antilymphocyte “induction,” is employed to prevent graft injury due to acute rejection.
 - 6 Prophylaxis against opportunistic infections includes agents targeted at common bacterial, viral, and protozoal pathogens.
 - 7 Although the number of heart transplants performed worldwide has declined due to a donor organ shortage, operative survival has improved over the past 20 years, and both patient and graft 1-year survival rates now exceed 87% for adults.
 - 8 Rejection and infection together account for most of the mortality during the first year after transplant, whereas long-term survival is limited by cardiac allograft vasculopathy (a manifestation of chronic rejection) and malignancy.
 - 9 Current initiatives in the field include development of improved immunosuppression (perhaps leading to graft “tolerance”) and alternatives to heart allotransplantation, such as “destination” mechanical support or heart “xenografts” from genetically modified pigs.
-

1 Since 1964, clinical cardiac transplantation has evolved from a sensational, perilous experiment to become conventional therapy for end-stage heart disease, the paradigm of successful but expensive “high-tech” medicine. This remarkable transformation stemmed from fundamental surgical innovations supported by incremental improvements in the diagnosis and management of common problems. Current challenges revolve around donor supply and allocation, improving long-term outcomes, developing alternative therapies, and related ethical issues.

HISTORICAL PERSPECTIVE

Based on significant contributions by many surgical pioneers,^{1–8} the first clinical heart transplant was performed in 1964 by Hardy,⁹ who attempted to salvage a man dying from cardiogenic shock by replacing his heart with one from a chimpanzee. Then, before the concept of brain death achieved wide social or legal acceptance, in 1967 Christian Barnard et al.¹⁰ captured the imagination of the world with the first operative survival, using the heart of a resuscitated cadaveric donor. This case, and many others that were performed shortly thereafter, demonstrated not only the physiologic capacity of the transplanted human heart allograft to support the recipient’s circulation but also the difficulty of diagnosing and managing subsequent immunologic and infectious complications. After a worldwide flurry of activity, generally dismal outcomes at many prominent cardiac surgery centers made clear the

need for more thoughtful approaches to what was clearly a difficult constellation of problems beyond effective circulatory support.

A few pioneering programs persisted in cautious clinical application supported by parallel laboratory investigation. Recognizing the need for a more sensitive and specific diagnostic technique to diagnose rejection, Phillip Caves, working with Shumway et al. at Stanford, developed the technique of transvenous endomyocardial biopsy.¹¹ Frequent, representative surveillance sampling of the graft allowed early detection of pathogenic host immune responses. Perivascular lymphocytic infiltrates were found to accurately diagnose acute cellular rejection in its presymptomatic phase; when detected early, rejection usually responded to enhanced immunosuppression. Equally important, when rejection was not seen, immunosuppression could be tapered to minimize drug toxicities and reduce the incidence of opportunistic infection. Coupled with important advances in the diagnosis, prevention, and treatment of infectious pathogens in immunosuppressed patients and in selection and management of patients with end-stage heart failure, patient survival at 1 year improved gradually, from about 20% in the 1960s to about 70% by 1980.¹²

However, even as recently as the early 1980s, when rejection persisted or recurred despite high-dose steroids, alternative treatments (total lymphoid irradiation, intramuscular antilymphocyte preparations, thoracic duct ligation, splenectomy) were often toxic or invasive and accompanied by a high incidence of major short- and long-term complications. In this context the discovery and clinical development of the first calcineurin inhibitor (CNI), cyclosporin A (CsA),^{13,14} catalyzed the next major improvement in outcomes. CsA's primary mechanism of action and toxicity profile were fundamentally different from those of azathioprine, the most commonly used antimitotic agent, or anti-inflammatory steroids and combination "triple" therapy allowed each agent to be used at lower doses and thus more safely. Meanwhile, antithymocyte and antilymphocyte preparations were adapted for safe intravenous use, either as prophylactic "induction" therapy ("quadruple therapy") or as treatment for steroid-resistant rejection. Based primarily on these pharmacologic innovations in the regulation of the immune response, expected 1-year survival following heart transplant gradually rose from about 70% to almost 90% between 1980 and the present, despite increasing reliance on older donors for older and sicker recipients.^{15,16}

CANDIDATE EVALUATION

End-stage heart failure is the primary indication for heart transplantation in adults, with coronary artery occlusive disease and myopathy of various etiologies each accounting for about 45% of cases. Congenital heart disease is the primary indication for infants, whereas myopathy predominates in older children.

2 heart transplant evaluation process seeks to identify patients who are at higher risk of death without transplant than with it and for whom no other reasonable treatment options exist, while excluding those whose comorbid conditions are likely to significantly limit length or quality of life. In 1993, a National Institutes of Health consensus conference developed recipient selection guidelines for cardiac transplantation, based on objective criteria known to predict poor outcome without transplantation¹⁷; these guidelines (Tables 38-1–38-3) continue to evolve in the context of improving heart failure therapy.^{18–20} Among patients with heart failure symptoms, maximal oxygen consumption (MVO₂) is more sensitive and specific than ejection fraction in gauging prognosis, and blunted cardiac output response to exercise may further stratify patients into high- and low-risk groups.¹⁸

When no clear survival advantage is apparent for transplantation or an alternative management strategy, quality of life and other subjective factors are weighed. Contemporary studies defining relative risks, along with basic considerations in the medical management of end-stage heart failure, are well summarized in recent reviews.^{19,20}

Table 38-1 Indications for Heart Transplant

General indications
End-stage heart disease without a lower-risk treatment alternative
Absence of any noncardiac condition likely to: 1. Limit survival independent of cardiac function 2. Preclude safe, reliable administration of adequate immunosuppression 3. Predispose to life-threatening infection or malignancy with immunosuppression
Specific indications 1. Heart failure of various etiologies a. Myopathy: ischemic, idiopathic, viral, familial, restrictive b. Valvular c. Congenital d. Failed transplant e. Early: primary nonfunction, acute rejection f. Late: cardiac allograft vasculopathy 2. Other indications a. Angina not amenable to revascularization b. Arrhythmia, failed conventional therapy c. Hypertrophic cardiomyopathy d. Restrictive cardiomyopathy e. Primary cardiac tumor (completely resectable)

Table 38-2 Selection Criteria for Stratifying Risk and Survival Results

Survival Benefit Established MVO ₂ <10 mL/kg/min Class IV CHF symptoms despite maximal medical therapy Requiring mechanical circulatory support Refractory angina without therapeutic alternative Refractory ventricular arrhythmia without alternative
Survival Benefit Likely MVO ₂ 10–14 with blunted CO response to exercise Instability of fluid balance or renal function despite documented compliance EF <20% with class III HF symptoms on maximal medical therapy
Survival Benefit Not Established MVO ₂ 10–14 with preserved CO response to exercise MVO ₂ >14, EF <20% without other indication History of CHF or arrhythmia, controlled with medical therapy Quality-of-life considerations may influence selection of recipients for whom survival benefit is not established.

CHF, congestive heart failure; CO, carbon monoxide; EF, ejection fraction; MVO₂, maximal oxygen consumption.

DONOR SELECTION AND MANAGEMENT

The ideal donor is a young, previously healthy individual without cardiac disease or hypertension, who is well matched in size to the intended recipient and whose hemodynamics have been carefully managed during the evolution of his or her lethal central nervous system (CNS) injury. Some programs have advocated use of older donors, donors who may transmit infection or malignancy to the recipient, and grafts with hypertensive myocardial hypertrophy for particular recipients.²¹ Some aggressive programs have even proposed that hemodynamically significant coronary stenoses can be bypassed at the time of transplant.²² These approaches to donor selection are associated with less favorable short- and long-term outcomes, but the increased risk may be considered acceptable for patients in whom the short-term prognosis is poor without transplant.^{15,23,24} Successful use of hearts resuscitated after cessation of cardiac activity in the donor has recently been described, and may prove to be safely enabled by functional and metabolic evaluation during normothermic ex vivo perfusion.²⁵ Survival of genetically modified pig hearts beyond 2 years in a preclinical model demonstrates significant progress toward an alternative potential solution to the organ donor shortage.²⁶

Donor management requires skill and experience to successfully address the complex physiologic perturbations associated with brain death. Reflex hypertensive and hypotensive responses to intracranial pressure changes, fluid and electrolyte imbalances consequent to the diabetes insipidus from pituitary death, and additional stresses related to hemorrhage, trauma, and surgery often cause hemodynamic and metabolic instability, which may injure a previously healthy heart. The neurohumoral milieu of CNS catastrophe may also adversely affect other fundamental cell regulatory functions, such as those dependent on thyroid hormone. Despite controversy regarding the mechanisms involved, thyroid

hormone is often administered to the donor as a continuous infusion, hoping to correct a “sick euthyroid” syndrome and optimize cardiac metabolism prior to explant. Although evidence to date is largely anecdotal, inotrope requirements can often be reduced after thyroid infusion is begun, and donor hemodynamic lability is less common, suggesting improved cardiac and vasoregulatory function.^{27,28}

Table 38-3 Contraindications to Cardiac Transplantation

Absolute contraindications ^a
High pulmonary vascular resistancea Transpulmonary gradient >15, fixed (unresponsive to Rx, mechanical unloading) Pulmonary vascular resistance index >5–6 Woods Units
Irreversible renal insufficiency (CrCl <40) ^a Active infection (viral or bacterial) Active peptic ulcer disease Diabetes with end-organ damage, renal insufficiency, neuropathy, retinopathy Symptomatic extracardiac vascular disease CVOd with recent TIA, CVA PVOD with claudication, rest pain, or tissue loss Mesenteric vascular disease with symptoms
Current malignancy or recent treatment (generally <2 yrs) for life-threatening malignancy Disease of another organ system that would probably limit survival Established cirrhosis, cardiac or other etiology Symptomatic COPD; chronic bronchitis High risk for inability to comply with complex medical regimen Not firmly committed to transplantation Inadequate cognitive capacity to comply with postop regimen, coupled with inadequate compensatory social support Documented psychiatric instability Recurrent drug or alcohol abuse Demonstrated noncompliance with therapeutic recommendations
Relative contraindications Age over 65 Established renal failure on stable dialysis (transplant-eligible) Diabetes without end-organ disease Asymptomatic or previously treated extracardiac vascular disease COPD with FEV ₁ or DLCO <60% predicted without referable symptoms Remote malignancy, in remission (generally >4 yrs with no evidence of disease) High pulmonary vascular resistance, reversible with Rx Disease of another organ system that would limit quality or length of life Difficulty complying with complex medical regimen
^a On optimal medical therapy and/or mechanical circulatory support. COPD, chronic obstructive pulmonary disease; CrCl, creatinine clearance; CVA, cardiovascular accident; CVOd, cerebrovascular obstructive disease; DLCO, carbon monoxide diffusing capacity; FEV ₁ , forced expiratory volume in 1 second; PVOD, pulmonary veno-occlusive disease; TIA, transient ischemic attack.

Cardiac echocardiography has become a standard component of donor assessment to measure ejection fraction and to exclude structural abnormalities or hypertrophy suggestive of hypertensive myopathy. Cardiac catheterization may be requested for donors over age 45, especially for those with a strong family history of coronary artery disease, for smokers, or when regional wall motion abnormalities are appreciated on echocardiography.

MATCHING DONOR TO RECIPIENT

Once a potential donor is identified, priority among blood type-compatible recipients is determined first by relative severity of illness (“status”) and then by length of time on the waiting list among those at each status in the donor’s geographic area. In the United States, this information is currently tracked and collated by a central, national registry operated by the United Network for Organ Sharing. The heart is first offered to the program whose candidate has priority on the list and whose registered height and weight range include the potential donor. Donor inotrope requirements and functional

assessment, recipient pulmonary vascular resistance, possible infection transmission risks (known hepatitis or potential human immunodeficiency virus [HIV] exposure in the donor), and other logistical considerations (expected graft ischemic time) influence the recipient team's decision regarding acceptance of an organ for an individual patient. If the first program declines the offer for the first patient, the process is repeated for the patient next on the list until the heart is accepted.

Tissue typing, the time-consuming process by which donor and recipient are matched for shared transplant antigens, is not currently used for hearts. The probability is low of identifying a "close" match among the relatively small number of blood type-compatible potential recipients within the geographic radius (usually <1,500 miles) defined by a 4-hour projected ischemic time. In addition, the demonstrated benefit of partial human leukocyte antigen (HLA) matching is small relative to the added risk of prolonged graft ischemia, a risk augmented by increasing donor age.^{16,29}

RECIPIENT MANAGEMENT BEFORE TRANSPLANT

3 The medical therapy of patients awaiting transplantation has improved significantly over the past decade, centered around aggressive afterload reduction and diuresis, anticoagulation, and beta blockade.^{18–20} This trend, coupled with improved mechanical support and improved donor allocation algorithms (discussed later), has reduced the mortality rate for patients awaiting transplantation. As waiting lists have grown faster than the donor pool and average time waiting has similarly escalated, cardiac decompensation among patients on the waiting list is frequent. In most areas of the United States and Europe, the majority of hearts go to patients who are sick enough to require hospitalization for intensive diuresis and intravenous inotrope administration.^{15,16}

When inotropic therapy proves inadequate, as gauged by progressive deterioration in renal and other end-organ function, temporary intra-aortic balloon pump counterpulsation and mechanical ventilation can stabilize some patients. These interventions are associated with important risks; the relative risk of death is increased threefold in patients who are ventilator dependent at the time of transplant.^{15,16} Consequently, mechanical circulatory support using ventricular assist device (VAD) blood pumps has emerged as an effective and generally preferred bridging strategy. Particularly in emergency circumstances or in the setting of progressive or refractory extracardiac organ dysfunction, temporary support with a paracorporeal (pump external to the body) VAD, an intravascular axial flow device (Impella), or with a venoarterial extracorporeal membrane oxygenator (ECMO) device, is used as a short-term "bridge to decision." Fully implanted pumps are reserved for patients for whom end-organ function seems likely to recover, and "bridge to transplant" (BTT) or definitive ("destination") VAD therapy is therefore deemed likely to extend life of a quality acceptable to the patient. Although many VAD-bridged patients incur serious complications (stroke, renal or hepatic failure, systemic infection, device malfunction) and some exhibit behaviors (noncompliance, substance abuse) that may preclude transplantation, about three quarters are successfully transplanted, with excellent outcomes relative to patients not requiring this intervention.¹⁶ Patients with biventricular failure can often be adequately supported with left ventricular support, with or without addition of temporary paracorporeal right heart support. Various total artificial heart devices can be implanted in place of the native heart and have been applied successfully in small numbers.^{30,31} This approach is most likely to find a niche as an alternative to heart transplantation in patients not supportable with a left VAD, such as those with fixed pulmonary hypertension, although BTT is the only application currently clinically approved by FDA. Over the past decade relatively small axial turbine (Jarvik 2000, HeartMate II) or bearing-free centrifugal (HeartWare) continuous-flow (nonpulsatile) VADs have largely supplanted bulkier (Novacor) or less durable (HeartMate I) pulsatile devices for both short-term paracorporeal (CentriMag) and longer-term applications. Continuous-flow assist systems have shown sufficient promise in clinical trials to earn FDA approval, with 1-year survival in both BTT patients and in carefully selected nontransplant-eligible "destination therapy" patients now approaching that observed after heart transplantation.^{32,33}

HEART PROCUREMENT

Cardiac allograft protection depends primarily on hypothermia, which reduces myocardial energy requirements while the heart graft has no nutritive coronary blood flow. Other important principles include avoidance of distention and warm ischemia in both the donor and the recipient and induction of diastolic (flaccid) cardiac arrest. These goals are accomplished by interrupting systemic venous return

for decompression, placing a clamp across the distal ascending aorta, and infusing a hyperkalemic preservation solution proximal to the clamp, and thus selectively into the coronary arteries. Both the inferior vena cava and left atrium are incised (“vented”) to prevent distention of either ventricle. Some preservation solutions incorporating free radical scavenging molecules or other cytoprotective agents are associated with improved early graft function.^{34,35}

Every effort is made to minimize the ischemic interval – the time between initial interruption of coronary flow by aortic cross-clamping in the donor and removal of the cross-clamp in the recipient – since recipient morbidity and mortality increase with each additional hour of “cold ischemic time.” Although laboratory studies and isolated clinical reports suggest that good results may be expected with storage times of 8 hours or more using various preservation solutions, increased ischemic time remains a strong and important independent risk factor for poor recipient outcome.^{15,16} Normothermic (~34 to 37°C) ex vivo organ perfusion during transport is being explored in clinical trials as a potential alternative to static cold storage (~4°C).³⁶

OPERATIVE RECIPIENT MANAGEMENT

Timing of the recipient operation requires careful coordination with the procurement team. Anesthesia is induced after the donor heart is visually inspected and found suitable. Venous access is obtained, which will permit rapid volume resuscitation and invasive cardiac monitoring after the new heart is implanted. Prior cardiac surgery may complicate coordination of operative timing and is associated with increased risk of bleeding.

Figure 38-1. Native cardiectomy and donor graft preparation. **A:** Recipient pericardium after institution of cardiopulmonary bypass and ascending aortic occlusion, with caval snares secured. The diseased native heart can then be safely excised by transecting the recipient aorta and pulmonary artery, and the atria divided as appropriate for the intended implant technique. Shown is the right atrial incision for the traditional Lower/Shumway right atrial cuff. **B:** Posterior view of the explanted donor heart, indicating various incisions used for atrial cuff preparation. Donor atrial cuff incisions made in preparation for traditional Lower/Shumway biatrial implant are indicated by the *heavy white dashed line*. The superior vena cava (SVC) is ligated or oversewn. Right and left pulmonary vein (*light white dashed line*) and superior vena cava (*black dashed line*) incisions are indicated for the total atrioventricular implant technique. For the bicaval technique, the donor SVC (*black dashed line*) and inferior vena cava are retained as for the total atrioventricular technique (Fig. 38-4), and the donor left atrial cuff trimmed as for the traditional biatrial approach (*heavy white dashed line*).

Figure 38-2. Traditional Lower/Shumway biatrial technique. **A:** Recipient cuffs, prepared for bicaval atrial implant technique. After completion of the left atrial anastomosis (**B**), the right atrial cuffs are joined. Care is taken to avoid carrying the right atrial incision or suture line close to the donor sinoatrial node, at the superior vena cava/right atrial junction (*asterisk*). **C:** Appearance of the operative field after completion of great vessel anastomoses, weaning from cardiopulmonary bypass, and decannulation.

If appropriate, Coumadin effects are reversed with fresh frozen plasma, vitamin K, or prothrombin complex concentrates. ϵ -Aminocaproic acid or tranexamic acid, and des-deoxyargine vasopressin (DDAVP) are often used to inhibit fibrinolysis and promote coagulation at physiologically appropriate sites, respectively, after prior cardiac surgery or associated with hepatic congestion. (Aprotinin, a serine protease inhibitor formerly in routine use to prevent coagulopathic bleeding, was withdrawn from the market because of safety concerns.) Increased inotropic infusion, antiarrhythmic agents, or mechanical circulatory support may be required to maintain adequate systemic perfusion prior to institution of cardiopulmonary bypass.

Vascular access for bypass is accomplished by cannulation of the superior and inferior vena cavae so as to completely divert systemic venous blood to the cardiopulmonary bypass circuit. The ascending aorta, common femoral, or subclavian artery is used for arterial return from the circuit to the patient. Technical misadventures – such as entry into the heart or great vessels before bypass is established or induction of ventricular arrhythmias – are more common with reoperative procedures, and can greatly complicate the intraoperative course and postoperative management.

Once the proximate arrival of the donor heart is ensured, the recipient is placed on bypass and cooled. Snare are secured around the caval cannulae, the ascending aorta clamped, and the native heart excised (Fig. 38-1A). Vascular cuffs are preserved and tailored appropriately for implantation of the donor heart (Figs. 38-2A, 38-3A, and 38-4A). The donor heart is then prepared according to the implant technique to be used (Fig. 38-1B).

Implant techniques and the sequence of vascular anastomosis vary widely between surgeons, as do strategies used to protect the ischemic organ during implantation. The biatrial orthotopic heart transplant technique is simple, easy to teach, and still used by many surgeons (Fig. 38-2A–C).⁸ The donor atria are spatulated open, trimmed if necessary, and laid over the recipient's atrial remnants. The left atrial suture line is everted to achieve endothelial apposition and to avoid leaving epicardial fat or muscle exposed in the lumen as a potential nidus for thromboemboli. Sinoatrial node dysfunction can usually be prevented by keeping the donor right atriotomy well anterior on the right atrial appendage,

away from the sinoatrial node and its blood supply (Fig. 38-2B), and by optimizing graft preservation.³⁵ Even if most of the dilated native atrium is excised, atrioventricular (AV) valve annular geometry may be distorted, causing tricuspid regurgitation; or the area around the sinus node may be placed under tension, leading to atrial arrhythmias or sinus node dysfunction.

Figure 38-3. Bicaaval right atrial implant technique. **A:** During explantation of the native heart, the interatrial septum may be excised, for end-to-end anastomosis of the cavae (**B**), or left in place (as in Fig. 38-2A), allowing the back walls of the donor cavae to be laid into those of the recipient. **C:** Technique for pulmonary artery venting through an opening in the anterior aspect of this anastomosis, which is useful for de-airing and decompressing the right heart. Alternatively, the aorta may be anastomosed earlier in the operation and the aortic cross-clamp removed, to minimize graft ischemic time.

4 During the 1990s, these considerations led to evaluation of alternate atrial anastomotic techniques, including bicaaval right atrial connections (Fig. 38-3A–C) and total atrioventricular replacement (two caval and two pulmonary vein anastomoses) (Fig. 38-4A, B). In a prospective, randomized trial (bicaaval)³⁷ and several retrospective analyses,^{38,39} the incidence of atrial arrhythmias and AV valve regurgitation was reduced, and hemodynamic results and survival were improved with either the bicaaval or total atrioventricular technique. Tricuspid valve annuloplasty may decrease early or later tricuspid regurgitation and reduce the incidence of right heart dysfunction.⁴⁰

Independent of whether the aorta or pulmonary artery connection is performed first, the anterior aspect of the pulmonary artery anastomosis is usually left open or vented, to allow decompression of the right heart after reperfusion (Fig. 38-3C). The size mismatch between donor and recipient aortas is often dramatic, but can usually be accommodated by beveling the smaller vessel (usually the more pliable donor) to increase its effective circumference and by distributing the discrepancy evenly over the length of each anastomosis. Occasionally it is necessary to tailor down the larger vessel to reduce its effective diameter, or to replace an aneurysmal ascending aorta with donor tissue or a prosthetic graft. Functional supra-avalvular pulmonary stenosis is avoided by trimming back both donor and recipient sufficiently to prevent redundancy or kinking.

An alternate “heterotopic” implantation technique places a second heart in the circulation, in parallel

with the retained native heart.⁴¹ In principle, leaving the native heart affords protection in the event that the graft fails. The operation is technically demanding, usually produces compressive atelectasis in the right lung, and is associated with a high risk of stroke, perhaps due to stasis of blood in the native heart.⁴² Notwithstanding, this surgical approach may be considered for patients with high pulmonary vascular resistance unresponsive to vasodilators, and may in the future also find a role in the initial application of cardiac xenografts.

After completion of the anastomoses, the heart is reperfused and allowed to resume contracting without being required to function as a pump (“rested”) as the recipient and graft are rewarmed. Atrial and ventricular pacing wires are placed. Cardiac output of the denervated transplant is highly dependent on rate. In addition, the shorter cardiac filling time associated with higher heart rate prevents graft distention. One commonly used protocol initiates isoproterenol prior to weaning from bypass at a dose of 0.005 to 0.02 µg/kg/min, titrated to achieve a heart rate of about 110 beats/min.

Figure 38-4. Total atrioventricular transplant technique. **A:** Recipient pericardial well after preparation of bilateral pulmonary vein pedicles and caval cuffs, for total atrioventricular heart transplant. **B:** Construction of left pulmonary vein anastomosis. As with other left atrial anastomotic approaches, atrial walls or vein cuffs are everted to minimize exposure of thrombogenic fat or muscle to the blood.

Patients with high preoperative pulmonary vascular resistance may be particularly difficult to wean from cardiopulmonary bypass, even with excellent function of the donor heart, as the “normal” donor right ventricle may acutely dilate and fail when confronted by a high-resistance pulmonary vascular bed. Resting the recently ischemic heart on cardiopulmonary bypass, establishing a stable sinus or AV sequentially paced rhythm, instituting inotropic support, and intra-aortic balloon counterpulsation are useful in managing this problem. Traditional pharmacologic approaches to reducing pulmonary vascular resistance, such as prostaglandins E₁ or I₂ and sodium nitroprusside, may cause transpulmonary shunting of deoxygenated blood; these agents also reduce systemic vascular resistance and thus coronary perfusion pressure. Inhaled nitric oxide or prostacyclin selectively dilates the pulmonary vascular bed before being rapidly inactivated, and is very helpful to selectively reduce pulmonary vascular resistance without adverse effects on systemic vascular resistance, oxygenation, or myocardial function.^{43,44} Poor graft function may necessitate institution of mechanical support (VAD support of one or both ventricles, or venoarterial ECMO) as a bridge to graft recovery or to retransplantation.

Postoperatively, ventilator and inotropic support is weaned, immunosuppression is instituted, and diuretic and antihypertensive agents are initiated as necessary. When used, isoproterenol is continued for about 5 days. Theophylline may be used transiently (for days to weeks after transplant) to sustain a resting heart rate over 70. The first surveillance endomyocardial biopsy is typically performed 7 to 14 days after surgery and repeated about every 2 weeks for the first 3 months. Patient and caregiver education with regard to medication schedules and physiologic monitoring facilitates early discharge for patients without complications. Biologic monitoring of peripheral blood gene or protein expression or lymphocyte function and electrical approaches to monitor the immune response to the graft have shown promise to safely reduce dependence upon routine invasive monitoring.^{45–48}

IMMUNOSUPPRESSION

5 The goal of immunosuppressive therapy is to prevent immune-mediated injury to the graft while minimizing associated complications, including opportunistic infection and drug-related toxicities. Most programs employ a “triple-drug” regimen, including a CNI, an antimitotic agent, and steroids. This approach allows each individual drug to be used within its therapeutic window (Table 38-4). Some centers add antibody “induction” with anti-interleukin-2 (anti-IL-2) receptor antibodies, polyclonal antilymphocyte serum, or other agents.^{15,16,49–54} Once wound healing has occurred, an inhibitor of the mammalian target of rapamycin (mTOR) may be introduced.⁵⁵ The mechanisms of action and side effect profiles of these agents are well described in an earlier chapter of the transplantation section of this text.

6 Medical management after heart transplantation is focused on anticipation and prevention of common complications. Hypertension and hyperlipidemia are prevalent due to predisposition in the recipient patient population and as side effects of various immunosuppressive agents. Prophylaxis against opportunistic infections includes agents targeted at common protozoal and viral pathogens (Table 38-4). Surveillance biopsies are performed according to a scheduled routine and additional biopsies are performed to exclude rejection in the event of hemodynamic instability or unexplained fever. Typically, patients are able to leave the hospital within 10 days of uncomplicated operation, to be followed regularly in outpatient clinic. Monitored physical rehabilitation facilitates optimal cardiovascular and musculoskeletal recuperation,⁵⁶ and occupational rehabilitation may offer important psychological and social benefits.

Table 38-4 Typical Immunosuppressive Protocol and Associated Medical Treatment Following Adult Heart Transplantation

Calcineurin inhibitors	Cyclosporine	2–4 mg/kg PO bid or 1–4 mg/h IV target trough level 250–500
	FK506	0.025–0.15 mg/kg PO bid target trough level 4–12
Side effects	Hypertension, renal insufficiency, tremor, neurotoxicity (FK>CsA) Hirsutism (cyclosporine A only), gingival hyperplasia, diabetes (FK only)	
Antimitotic agents	Azathioprine	1–2 mg/kg/d qd
	Mycophenolate mofetil	500–1,500 mg/d bid <i>occasionally regulated by drug levels</i>
Side effects	Marrow suppression, nausea, abdominal cramps, diarrhea <i>Dosing typically titrated based on bone marrow suppression</i>	
Mammalian target of rapamycin inhibitors	Sirolimus, Everolimus	0.5–5 mg/kg PO bid target trough level 4–12
Side effects	Delayed wound healing; Lymphedema; deep venous thrombosis; thrombotic microangiopathy	
Glucocorticoids	Methylprednisolone IV, then Prednisone PO	
Side effects	Hypertension, insulin resistance, osteoporosis, mood swings Central obesity, Cushingoid habitus	
Antiprotozoal	Trimethoprim–sulfamethoxazole (<i>Pneumocystis</i> ; toxoplasmosis)	
Side effects	Marrow suppression, renal insufficiency	
Antiviral	Acyclovir (herpes) Ganciclovir, valganciclovir (cytomegalovirus)	
Side effects	Marrow suppression	
Antihypertensives	Angiotensin-converting enzyme inhibitor or receptor blocker Diltiazem (retards CNI metabolism) α -Receptor blockers	
Antilipid agents	Statin class agent	

COMPLICATIONS

Complications of antirejection therapy relate primarily to the side effects of the specific immunosuppressive agents currently used. Infections tend to occur in patients with the greatest degree of preoperative debility and malnutrition, or in conjunction with additional stressors such as perioperative bleeding or hepatorenal dysfunction. Bacterial pathogens are common in the first several weeks, particularly in the lung and related to surgical or vascular access sites. Opportunistic viral and fungal infections usually predominate later. Increasingly effective prophylaxis for cytomegalovirus and herpes infections has markedly reduced the morbidity associated with these common pathogens. When infection occurs, immunosuppression is tapered as aggressively as possible based on myocardial biopsy

results.

Acute rejection occurs in the majority of patients and is graded histologically according to standardized criteria developed by the International Society for Heart and Lung Transplantation (ISHLT).^{57,58} When detected at an early histologic stage (ISHLT grade 1R, Fig. 38-5) in an asymptomatic patient on surveillance biopsy, rejection will often respond to augmented oral steroids and/or an increased dose of CNI. When a higher grade of rejection is found (Fig. 38-6), when the infiltrate fails to resolve in response to initial interventions, or in the setting of depressed cardiac function or shock, high-dose intravenous steroids are administered and antilymphocyte therapy often added. Inotropic or mechanical support is instituted as needed in hopes of rescuing graft and patient. Antibody-mediated “vascular” rejection is now a well-recognized entity that, when suspected or confirmed based on immunohistochemical techniques or detection of increasing titers of antidonor antibody, may warrant introduction of cyclophosphamide or other agents with increased activity against B cells.⁵⁸

Figure 38-5. International Society for Heart and Lung Transplantation grade 1R – diffuse interstitial or focal perivascular infiltrate with rare or absent myocyte damage is characteristic of mild acute cellular rejection.

Figure 38-6. International Society for Heart and Lung Transplantation grade 3R – multifocal cellular infiltrate with focal myocyte necrosis, typical of severe acute cellular rejection.

Bradycardia is prevalent in the denervated heart for the first weeks after transplant, but a resting heart rate over 70 can usually be achieved by initiating a β -agonist such as isoproterenol or theophylline. Persistent bradycardia may be caused by ischemic, surgical, or immunologic injury to the sinus or AV nodes or by amiodarone leaching from stores accumulated preoperatively in body fat; pacemaker implantation may be necessary. Atrial flutter or fibrillation may occur spontaneously or herald acute rejection. This dysrhythmia can be difficult to manage because vagal denervation attenuates digoxin modulation of the typical rapid ventricular response. Most other agents traditionally used to treat atrial arrhythmias depress AV node conduction or myocardial contractility, particularly undesirable side effects in a recent heart recipient. Amiodarone is generally better tolerated, controls heart rate and promotes conversion to sinus rhythm, and has been used widely in this circumstance once absence of acute rejection has been confirmed.

Among patients who survive beyond the first year, the primary limits to long-term survival are cardiac allograft vasculopathy (CAV) and malignancy^{15,16,24} (Fig. 38-7). Current understanding of the pathogenesis of CAV is incomplete.^{59–61} Widely presumed to be a consequence of “chronic rejection,” this process has an incidence of approximately 5% per year. CAV may cause progressive insufficiency of coronary flow, myocardial infarction, and ultimately death. Recent research has drawn attention to the

importance of donor stress associated with brain death and ischemia/reperfusion injury in the incidence and severity of CAV in animal models.⁶² In contrast to the usual pattern of focal proximal lesions in conventional atherosclerosis, coronary arteries are diffusely involved and conventional revascularization techniques are not generally feasible. This process has proven stubbornly refractory to immunosuppressive or antiproliferative interventions.^{55,63} Both CAV and increased risk of malignancy would likely be prevented if durable tolerance were successfully induced, but this objectives has thus far proven elusive for the heart as for other organs.⁶⁴

RESULTS

7 Due to a decline in the number of donor hearts that are considered acceptable, the number of heart transplants performed worldwide has declined, from a peak of about 4,070 in 1995 to fewer than 3,200 reported in each year since 2000, a 20% decrease. While some decrease in reporting from European centers may have resulted from the absence of an incentive to contribute to international registries, reported U.S. activity – which is federally mandated by organ allocation regulations – decreased by about 15% between 1997 and 2004 despite a steady increase in average donor age.^{15,24} A slight upward trend in U.S. heart transplant activity during the past decade (from 2,000 to 2,200 cases annually between 2004 and 2014) may reflect the influence of a Health Resources and Services Administration organ donor initiative,^{15,65,66} and implementation in 2006 of a donor allocation algorithm that emphasizes recipient disease acuity over proximity to the donor hospital or other factors.

8 Operative survival in adults has improved over the past 20 years to above 90%, and both patient and graft 1- and 5-year survival rates exceed 87% and 75%, respectively (Fig. 38-8).^{15,16} The most important risk factors for death within the first year include previous transplant, increased donor age (with age older than 60 conferring greater risk than age older than 45), need for ventilator or left VAD support before transplant, and recipient age older than 60. Among common complications, rejection and infection together account for most of the mortality during the first year and contribute approximately equally (Table 38-5). Beyond the first year, malignancy including posttransplant lymphoproliferative disease and chronic rejection emerge as prominent additional factors limiting long-term survival. Extrapolating from current early results, more than 50% of recent recipients can expect to be alive 10 years after transplant, with actuarial graft half-life over 12 years.^{15,16,24,29}

Repeat heart transplantation accounts for less than 2% of all heart transplants done. When performed within the first 6 months, typically for early failure of the first graft, 1-year survival is less than 50%. When performed later, usually for cardiac allograft vasculopathy, 1-year survival is over 80%, and has improved significantly over the past decade. Overall, actuarial graft half-life following retransplant is about 4.6 years, and is over 9 years in those who survive the first year.¹⁶ While these outcomes are significantly inferior to other transplant indications, retransplantation offers significant survival advantage for carefully selected patients.

Figure 38-7. Autopsy specimen of an epicardial coronary artery demonstrating a moderately severe concentric fibroproliferative intimal lesion characteristic of cardiac allograft vasculopathy. (Courtesy of Dr. James Atkinson, Vanderbilt University School of Medicine, Nashville, TN.)

Figure 38-8. Heart Transplant Survival, 1980–2015. Survival following heart transplantation in recipients, grouped by era of operation, analyzed by the Kaplan–Meier method. Operative survival accounts for much of the steady improvement in outcomes over the past two decades. The subsequent rate of attrition appears to have changed little over the past 35 years, likely reflecting the effect of competing influences such as an older, sicker recipient population and improving patient management strategies. (Figure created from data provided by the United Network for Organ Sharing and International Society for Heart and Lung Transplantation, including follow-up information available as of April 2015.) Current demographics and statistics may be found at International Society for Heart and Lung Transplantation website (www.ishlt.org).

Table 38-5 Complications Following Heart Transplantation

Primary graft failure (<5%)
Technical (inadequate tissue preservation; reperfusion injury)
Immunologic (hyperacute rejection)
Donor selection (myocardial, valvular, or coronary obstructive disease in donor)
Technical
Size mismatch (too large, too small)
Bleeding (surgical, medical)
Anastomotic (narrowing, aneurysm, disruption)
Infection
Bacterial (various)
Viral (herpes, cytomegalovirus, Epstein–Barr virus)
Protozoal (toxoplasmosis, <i>Nocardia</i>)
Fungal (<i>Candida</i> , <i>Aspergillus</i>)
Treatment effects
Hypertension (99% by 10 yrs)
Hyperlipidemia (93% by 10 yrs)
Diabetes (37% by 10 yrs)
Renal failure (acute; chronic) (39% by 10 yrs; 6% dialysis or transplant recipient)
Malignancy (31% by 10 yrs)
Skin
Visceral (lung, colon, prostate/breast, other)
Lymphoproliferative disease

Adolescent (11 to 17 year olds) pediatric heart transplantation recipients fare better (>80% 1-year survival) than do younger children (1 to 10 year olds: ~77%) or infants (younger than 1 year old: ~68%). Less favorable short-term outcomes may be ascribed to pulmonary hypertension and anatomic challenges posed by congenital heart disease, and to monitoring and compliance challenges characteristic of these age groups. Nonetheless, the graft half-life for pediatric patients (11.4 to 13 years) is similar to that for adults.^{15,16,24,29}

ETHICS

Ethical considerations are important to every aspect of heart transplantation. The donor pool is limited and appears to be shrinking despite extended donor acceptance criteria, restricting the number of patients who can undergo transplantation. This shortage forces consideration of ways to limit recipient candidacy (age limits), to increase the donor pool (presumed consent, advertising initiatives, community outreach), and to develop alternatives (mechanical devices, xenografts, bioengineered hearts).^{26,33,67–70}

The heart transplant community has taken the lead in standardizing patient selection and management guidelines and has established policies for equitable organ allocation. Those given an opportunity to receive the “gift of life” are chosen from a much larger population who might benefit. Recipient candidacy decisions are made by a multidisciplinary group based on objective and subjective input from many individuals who come to know the patient and family in depth. Some recipient selection criteria are fundamentally arbitrary: for example, age is retained as a criterion because of the limited supply of donor organs and based on the consensus view that younger patients deserve preferred access. Recipient selection criteria only become unfair if they are applied unequally or inconsistently at different programs or between various regions of the country.

Some of the most difficult decisions made by the heart transplant team involve medically marginal candidates with outstanding and effective social support or medically suitable candidates with marginal social support. While the majority of such patients will do well, outcomes in either case can, on average, be expected to fall below outcome benchmarks. For every marginal patient transplanted, a candidate who meets all the criteria may die. Thus, the “right” decision for an individual patient is difficult or impossible to know in advance and may conflict with the best interests of the population of potential recipients.

CURRENT ISSUES

Quantifiable, objective measures of efficacy beyond survival, such as improvement in exercise capacity, freedom from complications, and reduced costs are becoming the standards by which individual heart transplantation programs are judged. Most important to the patient are subjective factors such as quality of life and productivity, for which standardized measurement tools are being developed. Meanwhile, the efficacy of any proposed alternative to transplantation must be measured against survival, cost, and quality-of-life benchmarks established by this once-experimental procedure.^{71,72}

The most important factor currently restricting the application of heart transplantation is the limited supply of donor organs. Consent is obtained from the donor’s legal representatives in only about 25% to 50% of cases where hearts are appropriate based on acceptable physiologic parameters. Various proactive approaches, such as institution of presumed consent, have been associated with high per capita donation rates in some countries. However, presumed consent is ethically dubious and may violate basic cultural or religious precepts of individuals or ethnic groups. An adverse societal response to imposition of this unpopular approach as national policy might paradoxically cripple efforts to maintain organ donation even at current levels. Well-conceived efforts to increase the rate of consent, by passing laws requiring hospitals to facilitate and document the request, by allowing trained individuals to manage the request process, and by educating the public about “the gift of life,” have boosted per capita donation in several U.S. organ procurement regions.

9 Efforts to develop improved immunosuppressive drugs are important and are likely to yield incremental near-term improvements in the incidence of chronic rejection. Ideally, one could induce tolerance – permanent graft acceptance without requirement for indefinite immunosuppressive therapy. Modulation, rather than suppression, of host responses to donor antigens may allow achievement of this goal.^{73,74}

Even if every physiologically suitable donor heart were available, only a minority of patients for whom transplantation would offer a survival advantage could be cared for using this modality. As technical innovations and management strategies evolve to address issues related to transcutaneous power delivery, thromboembolism, infection risk, and reliability, definitive “destination” therapy with VADs has become a viable option for some patients.³³ Progress has also been made toward use of porcine “xenografts” in man. The initial immunologic barrier, hyperacute rejection, appears surmountable using organs from pigs genetically modified to express human complement regulatory proteins and “knocked out” for the gene encoding Gal α 1,3Gal, the main carbohydrate target recognized by human antipig antibodies.^{26,69,75–79} Control of subsequent antipig antibody responses and coagulation

pathway dysregulation phenomena has been achieved in animal models, with recent survival of multitransgenic heart grafts beyond 2 years using an “experimental” but clinically applicable immunosuppressive regimen.²⁶ Meanwhile, fully life-supporting function of renal xenografts (for 3 months) and heart xenografts (for 1 month) have been demonstrated in primates using an intensive regimen of “conventional” immunosuppressive agents.^{78,79}

Heart transplantation is one of the most resource-intensive modalities in modern medicine when assessed as cost per year of life saved. The procedure itself, the increasingly common in-hospital and/or VAD bridge care before transplantation, and maintenance of program infrastructure are very expensive. Ongoing pharmacy charges and surveillance procedure costs are also substantial. Paradoxically, patients physically able to return to work often cannot do so because they rely on medical disability benefits to pay for medications and follow-up care. Whether heart transplantation will continue to receive wide support is a function of societal acceptance of these costs, as currently reflected by coverage policies established by public and private health care insurers.⁷¹ In the future the application of heart transplantation and related technologies may be limited more by what society chooses to afford, rather than what is medically possible.

Chapter 39

Pulmonary Transplantation

Jules Lin and Andrew C. Chang

Key Points

- 1 Candidates for lung transplantation have significant functional impairment that interferes with their activities of daily living. In patients with restrictive or obstructive pulmonary disease, gas exchange is impaired requiring supplemental oxygen while in pulmonary vascular disease, manifestations of right ventricular failure predominate.
 - 2 Initiation of the Lung Allocation Score (LAS) has decreased waitlist times and waitlist mortality while posttransplant survival has continued to improve. With an increased emphasis on waitlist survival and transplant benefit, there has been a shift in the primary diagnosis from emphysema to pulmonary fibrosis.
 - 3 Patients being listed for transplant are sicker than in the past with an increasing percentage of patients with an LAS score > 50, and with acute inpatient evaluations becoming more common, it is critical to avoid deconditioning by using aggressive physical therapy, early tracheostomy, and ambulatory extracorporeal membrane oxygenation (ECMO) when necessary.
 - 4 Advances in donor management and lung preservation have increased the number and quality of donor lungs and is likely responsible for the increase in the number of lung transplants performed over the last 10 years. Ex vivo perfusion of marginal donor lungs and the use of DCD lungs (donation after cardiac death [DCD]) may allow further increases in the percentage of recoverable lungs.
 - 5 Posttransplant lung injury results from the ischemic insult and subsequent reperfusion of the donor lung as well as the host immunologic response and other mediators of non-alloimmune-related injury.
 - 6 By the end of the first year after transplantation, approximately 80% of recipients report no limitations in activity.
 - 7 Long-term survival after lung transplant is lower when compared to outcomes after transplantation of other solid organs. The lack of effective medical therapy for chronic rejection remains a significant barrier and is the focus of ongoing research.
 - 8 Reflux in lung transplant patients has been associated with aspiration, impaired lung function, and decreased survival. Antireflux surgery decreases immune factors associated with bronchiolitis obliterans syndrome (BOS), preserves overall pulmonary function, and can be safely performed in lung transplant patients.
-

INTRODUCTION

The first lung transplant was performed by James Hardy in 1963 at the University of Mississippi in a patient with lung cancer who died 18 days later from renal failure.¹ Over 40 lung transplants were performed in the next 20 years with no long-term survivors. With time, pulmonary vascular and bronchial anastomotic techniques were refined including the telescoping bronchial anastomosis and wrapping the anastomosis with omentum to provide neovascularization. Steroids were found to inhibit bronchial healing,² and with the availability of cyclosporine and its decreased toxicity,³ the first successful lung transplant was performed in 1983 by Joel Cooper at the University of Toronto. The number of lung transplants continues to increase with approximately 3,640 lung transplants performed worldwide in 2011.⁴ Pulmonary transplantation comprises 4% of the organs transplanted in the United States.

Over the past 30 years, outcomes have improved dramatically, but even with advances in immunosuppression, surgical technique, and perioperative and posttransplant care, long-term survival

following pulmonary transplantation remains less than that of other solid organ transplants. The major factors limiting long-term survival include donor availability, recipients with more advanced disease, infection, acute rejection, impaired anastomotic healing,⁵ and chronic rejection with bronchiolitis obliterans.⁶ Survival continues to increase, and the median survival in 2013 was up to 5.6 years from 5.3 years in 2010.^{4,7}

The lung has a dual blood supply as a result of distinct bronchial and pulmonary arterial circulation. Bronchial artery reanastomosis has been proposed as a way to decrease ischemia to the anastomosis, but since bronchial artery anatomy and caliber vary greatly, most transplant surgeons have not advocated reanastomosis in order to limit prolonged ischemia times. Bronchial anastomotic healing is dependent on retrograde perfusion from collaterals from the pulmonary arterial circulation. Consequently, the bronchial anastomosis is more profoundly ischemic after transplantation and susceptible to airway dehiscence, typically within 3 weeks after transplantation. The combination of anastomotic ischemia and other factors such as infection and postreperfusion edema hindered initial efforts to develop successful clinical programs in pulmonary transplantation.

The first combined heart and lung transplantation was performed successfully in 1981, but this procedure is currently rarely performed, with only 23 performed in the United States in 2013. Combining cardiac and pulmonary transplantation introduced new issues including those associated with heart transplantation, especially accelerated coronary artery atherosclerosis. Impaired tracheal anastomotic healing is less common, possibly because the bronchial artery collaterals in the subcarinal space are preserved. The discrepancy between available donor organs and the increasing number of patients on the waiting list for heart or lung transplantation as well as lower short- and intermediate-term survival among heart–lung transplant recipients compared to heart or lung transplant alone are factors which have decreased the performance of heart–lung transplantation.

Investigators have defined factors contributing to failure in pulmonary transplantation.⁸ These factors include a significant detrimental effect of corticosteroids on airway healing. Investigators have also shown that cyclosporine did not have this adverse effect and that delaying the administration of maintenance corticosteroids was advantageous. Wrapping the bronchial anastomosis with a pedicle of omentum was initially thought to encourage capillary growth and promote airway healing, although this has not correlated with a reduction in anastomotic dehiscence.⁹

Another factor contributing to the improved success of lung transplantation was recognition of the importance of careful recipient selection. Most early attempts at pulmonary transplantation involved critically ill, ventilator-dependent patients who had already suffered significant physical debilitation. Poor short-term outcomes highlighted the importance of assessing preoperative functional status and implementing intense pulmonary rehabilitation pretransplant. Thorough patient evaluation and preparation, in addition to advances in operative techniques and immunosuppression, have improved outcomes and broadened the indications for pulmonary transplantation.

As lung transplantation became more widely accepted in the treatment of end-stage lung diseases, the worsening discrepancy between donor organ availability and patients listed for transplantation resulted in increasing waitlist mortality. Initial lung allocation policies were based on ABO blood type compatibility, geographic proximity to the donor hospital, and the accumulated waiting time since listing. In 1998, the Final Rule was issued by the U.S. Department of Health and Human Services requiring increased organ sharing with development of an organ allocation system that would be more equitable and that would reduce the use of waitlist time as a criterion for allocation.¹⁰ In 2005, the Lung Allocation Score (LAS) was implemented, incorporating waiting list and posttransplant survival probabilities, in order to minimize waiting list mortality, increase the benefit of transplantation among recipients, and ensure equitable allocation of lungs to lung transplantation candidates. Since implementation of the LAS, there has been a dramatic reduction in the duration of median waiting list time prior to transplantation, from 792 days in 2004 to 199 and 132 days in 2005 and 2006, respectively.¹¹ Waiting list mortality also declined from 134.6 per 1,000 patient-years in 2004 to 114.9 per 1,000 patient-years and 97.2 per 1,000 patient-years in 2005 and 2006, respectively.

INDICATIONS

1 Transplantation is indicated for patients with isolated organ dysfunction who have limited life expectancy despite maximal medical therapy (Table 39-1). A patient should be referred for lung transplantation when expected survival after transplant exceeds the expected survival without transplantation. Improvements in patient selection, operative techniques, organ preservation,

immunosuppression, and posttransplant management have led to better survival after transplantation. The overall median survival after transplantation is approximately 5 years, and the timing of transplant is an important consideration for maximizing transplant benefit. Prior to May 2005, allocation of donor lungs was based on time on the waiting list. With the large discrepancy between the number of listed transplant candidates and the limited availability of donor lungs, referral for transplant often occurred well before patients had become severely debilitated from poor respiratory function. With the institution of the LAS, the severity of disease has become a more important factor than waitlist times alone.

Lung transplantation can also provide considerable palliation for dyspnea. Due to the limited availability of donors, quality-of-life improvement has been considered secondary to survival benefit, although improved outcomes in terms of oxygen dependence, physical activity, and return to work remain important in assessing the success of pulmonary transplantation.

CONTRAINDICATIONS

Table 39-2 lists absolute and relative contraindications to lung transplant. The absolute contraindications are consistent with the risks associated with immunosuppression and the physical and social challenges of maintaining a complex medical regimen after transplantation. With respect to body mass index (BMI), extremes in weight have been associated with lower short-term survival in heart transplant patients.¹² These findings have been reinforced by studies of lung transplantation where extremes in BMI have been shown to confer a three- to fivefold increase in 90-day mortality.^{13,14}

Overall survival for patients over the age of 65 is significantly lower than for younger cohorts.^{15,16} A consensus report in 2006 recommended that age >65 be a relative contraindication¹⁷ due to lower survival with a median survival of 3.6 years and a 5-year survival of 38%. Many centers will limit listing recipients to those who are 65 years of age or younger. Despite this, the number of transplants in older patients has continued to increase, and single-institution studies have demonstrated similar 1- and 3-year survival in highly selected older patients.^{18–20} Since the implementation of the LAS, recipients age 65 or older have increased most rapidly from 2.9% in 1998 to 19% in 2008 and 25.9% in 2012.^{4,21–23}

Postoperative recovery after lung transplant can be particularly challenging. Incisional pain, impaired ventilatory mechanics, malnutrition, and deconditioning directly impact lung function as with any pulmonary operation. In the early days of lung transplantation, it became apparent that posttransplant survival was poor for ventilator-dependent patients or those with immunosuppression-related myopathy. Preoperative pulmonary rehabilitation and improved selection of ambulatory patients led to a significant improvement in survival in the 1990s. With improvements in critical care, pulmonary transplantation may still be appropriate in highly selected ventilator-dependent patients as demonstrated in small single-center series including patients who have had rapid deterioration in lung function and who have had only brief periods of debilitation. Adjuncts to mechanical ventilatory support, particularly tracheostomy or venovenous extracorporeal membrane oxygenation (ECMO),²⁴ may allow patients to continue efforts to maintain preoperative conditioning. While patients with end-stage extrapulmonary organ dysfunction are generally not candidates for lung transplant, limited experience has demonstrated acceptable survival in patients with coronary artery disease amenable to coronary artery bypass grafting or percutaneous coronary intervention.²⁵

Table 39-1 Pulmonary Disease Diagnosis Groups

Group A	Group B	Group C	Group D
Chronic obstructive pulmonary disease	Primary pulmonary hypertension	Cystic fibrosis	Idiopathic pulmonary fibrosis
Alpha-1 antitrypsin deficiency	Pulmonary thromboembolic disease	Hypogammaglobulinemia	Interstitial pneumonias
Sarcoidosis (mean PA pressure <30 mm Hg)	Pulmonary veno-occlusive disease	Common variable immune deficiency	Sarcoidosis (mean PA pressure >30 mm Hg)
Bronchiectasis	Eisenmenger syndrome		Connective tissue diseases
Lymphangioleiomyomatosis	Pulmonic stenosis		Amyloidosis
			Eosinophilic granuloma
			ARDS/pneumonia

PA, pulmonary arterial; ARDS, acute respiratory distress syndrome.

Table 39-2 Contraindications to Lung Transplantation

Absolute Contraindications
Recent malignancy other than skin cancer (nonmelanoma)
End-stage extrapulmonary organ dysfunction (i.e., cirrhosis, dialysis-dependent renal failure)
Active sepsis
Active HIV infection
Active hepatitis B or C infection with histologic evidence of liver damage
Current or recent tobacco use
History of alcohol or drug abuse/addiction
Severe psychiatric illness
History of noncompliance with medical therapies
Malnutrition (BMI <18)
Relative Contraindications
Age >65
Debilitation (6-min hall walk <150 m)
Mechanical ventilation
Extrapulmonary organ dysfunction
Uncorrectable coronary artery disease
Severe esophageal dysmotility
Severe osteoporosis
Poorly controlled chronic medical conditions (e.g., diabetes, hypertension)
Chronic high-dose steroid dependence
Chest or spinal deformity
Obesity (BMI >32)
Severe pleural disease including empyema, fungal infection, and pleurodesis
Chronic infection with HIV or hepatitis B or C

BMI, body mass index; HIV, human immunodeficiency virus.

Disease-Specific Indications

Disease-specific indications for lung transplantation are listed in [Table 39-3](#).

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) was the most common indication for lung transplantation prior to the institution of the LAS score, accounting for 35.4% of transplants from 1990 to 2004 and decreasing to 30.9% after 2005.¹⁵ Advances in medical therapy for patients with emphysema that can prolong survival include smoking cessation, long-acting bronchodilators, oxygen supplementation, optimization of nutrition, pulmonary rehabilitation, and vaccination for pneumonia and influenza. In addition, lung volume reduction surgery confers a survival benefit in patients with upper lobe–predominant disease, impaired exercise capacity, and the absence of high-risk factors including forced expiratory volume in 1 second (FEV₁) less than 20% or carbon monoxide diffusing capacity (DLCO) less than 20%.²⁶ Patients who deteriorate despite maximal therapy and who are not candidates for lung volume reduction should be referred for transplantation.

Factors associated with poor survival in patients with COPD include respiratory exacerbation with hypercapnia, hypoxia, pulmonary hypertension, increasing age, decreasing FEV₁, decreasing DLCO, and increased BMI.²⁷ A prospectively validated index based on body mass, airflow obstruction, degree of dyspnea, and exercise tolerance (BODE) has been proposed as a robust predictor of mortality in patients with COPD. A BODE index of greater than 7 on a scale from 0 to 10 was associated with a median survival of 3 years.²⁸

Idiopathic Pulmonary Fibrosis

Usual interstitial pneumonia (UIP) is the pathologic correlate of idiopathic pulmonary fibrosis (IPF) and is the most common subtype of interstitial lung disease. While IPF accounted for 28% of single lung transplants and 14% of bilateral lung transplants from 1995 to 2007, pulmonary fibrosis has become the most common indication for lung transplantation after the initiation of the LAS with 32% of all lung transplants performed for IPF in 2006 and 36.5% in 2013.^{16,29}

Table 39-3 Disease-specific Considerations for Lung Transplantation

Chronic Obstructive Pulmonary Disease BODE index >7 or hospitalization for exacerbation with hypercapnia (PaCO ₂ >50 mm Hg) Pulmonary hypertension FEV ₁ <20% and either DLCO <20% or non-upper-lobe-predominant emphysema
Idiopathic Pulmonary Fibrosis Histologic or radiographic evidence of UIP and: DLCO <39% >10% decrease in FVC on 6-mo follow-up SaO ₂ <88% during a 6-min walk test “Honeycombing” on HRCT (fibrosis score ≥2)
Cystic Fibrosis FEV ₁ <30% or rapid decline in FEV ₁ on follow-up Exacerbation requiring ICU stay Increasing frequency of exacerbations Refractory or recurrent pneumothorax Increasing oxygen requirements Hypercapnia Pulmonary hypertension
Idiopathic Pulmonary Hypertension NYHA class III or IV on maximal therapy Low or declining 6-min walk test Cardiac index <2.0 Right atrial pressure >15

BODE, body mass, airflow obstruction, degree of dyspnea, and exercise tolerance; DLCO, carbon monoxide diffusing capacity; FEV₁, forced expiratory volume in 1 second; HRCT, high-resolution computed tomography; NYHA, New York Heart Association; UIP, usual interstitial pneumonia.
Taken from Orens JB, Estenne M, Arcasoy S, et al. International guidelines for the selection of lung transplant candidates: 2006 update—a consensus report from the Pulmonary Scientific Council of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant* 2006;25(7):745–755.

Although the options for effective medical therapy for IPF are limited and patient mortality is high with a median survival of 3 to 4 years following diagnosis, patients experience a variable clinical course, with some patients progressing rapidly and others with a more gradual decline. Risk factors for poor survival include a pathologic diagnosis of UIP as opposed to other types of interstitial lung disease, severe fibrosis by high-resolution CT scan, the presence and severity of pulmonary hypertension, and acute pulmonary exacerbations.

Assessment of pulmonary function and exercise capacity can also be used to identify patients at higher risk for mortality. A baseline DLCO of less than 39% and a greater than 10% decrease in DLCO or forced vital capacity (FVC) over a 6- to 12-month period are associated with an increased risk of death.^{30,31} Oxygen desaturation and a shorter 6-minute walk distance independently predicted increased mortality in patients with pulmonary fibrosis.³²

Lung transplant improves survival and quality of life in patients with end-stage interstitial lung disease with a median survival of 4.5 years which may be affected by the increased age at diagnosis.³³ Prior to the LAS, IPF patients had the highest waitlist mortality rate^{34,35} and decreased survival in the early posttransplant period compared to other diagnoses.³⁶ The development of pulmonary hypertension significantly increases the risk of complications and decreases survival.³⁷ LAS scores have increased since 2005 for patients with IPF to 43.3 compared to 38.3 with no change in postoperative mortality while waiting times have decreased from 266 days to 78 days.²⁹

Cystic Fibrosis/Bronchiectasis/Infection-Related End-Stage Lung Disease

Cystic fibrosis (CF) is the third most common indication for lung transplantation, accounting for 16.3% of lung transplants performed in the last 15 years with a median survival of 7.8 years, with most recipients undergoing bilateral transplantation due to the risk of bacterial seeding of the transplanted lung.¹⁶ Colonization of the airway with resistant organisms is common in these patients and is not an absolute contraindication to transplantation, although sepsis is an absolute contraindication. Single-institution studies have identified colonization with *Burkholderia cepacia* genomovar III (redesignated as *Burkholderia cenocepacia*) to be associated with a 30% to 40% increase in posttransplant mortality, although this finding has not been validated in a multi-institutional setting.

Among patients with pulmonary disease due to CF, the time course of respiratory deterioration is highly variable making the criteria for pulmonary transplantation in this population difficult to define by risk modeling. Deterioration of FEV₁ to below 30% of predicted remains an indication for referral for evaluation, although not necessarily for immediate listing.^{38,39} Other factors to consider include

increasing oxygen requirements, hypercapnia, and pulmonary hypertension.⁴⁰

Pulmonary Artery Hypertension

Idiopathic pulmonary artery hypertension (PAH) has a median survival of less than 3 years if untreated, and the cause of death in most patients is progressive right-sided heart failure. Pulmonary hypertension was a more common indication for transplantation in the past, and after the initiation of the LAS, the percentage of transplant patients waitlisted has decreased from 14.7% in 2002 to 10.8% in 2007 and 6.4% in 2012.²³ There has been some concern that the LAS may not adequately prioritize these patients. Increasing use of medical vasodilator therapy including inhaled iloprost and oral sildenafil, prostacyclin analogs, phosphodiesterase 5 inhibitors, endothelin receptor antagonists, and guanylate cyclase stimulators have improved survival in this population and may also be responsible for the decrease in transplants performed for PAH. Patients with a history of right heart failure or poor pretreatment functional status and those with either no response or functional deterioration despite vasodilator therapy should be referred for transplantation. Recent guidelines emphasize progressive deterioration of right heart function despite maximal medical therapy as an indication for referral.⁴⁰

Cardiac index is an independent predictor for improvement in survival in patients with PAH.⁷ Patients with left ventricular heart failure requiring inotropic support may not be suitable candidates for pulmonary transplantation alone but instead should be considered for heart–lung transplantation. Patients with PAH made up 23% of heart-lung transplant recipients from 2000 to 2012.⁴

Lung Allocation and Transplant Benefit

Lung Allocation Score

The goal of the lung allocation system should be to maximize the net benefit for donated lungs. Before 1995, allocation was based solely on wait times, geography, and blood type. In 1995, an exemption was created for an additional 90 days for idiopathic pulmonary fibrosis due to increased mortality for these patients on the waitlist. However, this did not account for differences in mortality for other pulmonary diseases. The allocation system preferentially selected patients with a longer survival, and the waitlist times were greater than 2 years for the majority of listed patients. Due to the increasing number of waitlist deaths, the Final Rule was instituted in 1998 and mandated that medical necessity be considered in organ allocation.^{35,41}

In compliance with the Final Rule, the LAS was developed and has been one of the most significant changes in the practice of lung transplantation over the past 10 years. The LAS was implemented in 2005 and takes into account the urgency (1-year risk of dying on the waitlist without a transplant) and utility (1-year survival posttransplant) giving a net transplant benefit. The normalized LAS ranges from 0 (lowest priority) to 100 (highest priority) for recipients older than 12. The waitlist mortality is given a greater weight in the LAS score. Variables included in the LAS score are listed in Table 39-4.

Lung allocation currently depends on the LAS, blood type, recipient and donor size, geographic location, and age, with donor lungs being offered first to local candidates who are ABO identical and then to patients that are ABO compatible. The donor lungs are then offered to zones A–E, increasingly further away from the donor center. Since the initiation of the LAS, PaCO₂ values and bilirubin were added in 2008 while FVC was removed for all groups except group D. The bilirubin has a high impact on potential recipients with idiopathic pulmonary hypertension (group B).

Table 39-4 Selected Components of the Lung Allocation Score

Age
Bilirubin
Cardiac index, CVP
Diagnosis group
Functional status
Diabetes
Assisted ventilation
Supplemental oxygen
FVC% predicted (Group D)
PA systolic
PA mean
PA wedge
PaCO ₂ (≥40 or increase ≥15%)
6-min walk
Creatinine

FVC, forced vital capacity; PA, pulmonary artery.

Transplant Benefit

Egan et al.¹⁰ analyzed over 4,000 patients on the lung transplant waiting list in order to identify markers of waitlist mortality in the Scientific Registry of Transplant Recipients (SRTR). The listing diagnoses for these patients, including COPD, IPF, CF, and PAH, accounted for 80% of the transplants performed at the time. Transplant candidate demographics, hemodynamic parameters, measures of pulmonary function, and other clinical variables were used to create a regression model. Substantial differences in waitlist mortality were found, with patients listed for emphysematous diseases experiencing a 1-year waitlist mortality of less than 14% compared with 1-year waitlist mortality between 28% and 33% among patients listed with the other three primary diagnoses. These results were confirmed in the International Society of Heart and Lung Transplantation (ISHLT) Registry data from 2005 showing that patients with IPF, PAH, and sarcoidosis had an increased relative risk for 1-year waitlist mortality and a waitlist mortality of 9.7%, 13.1%, 17.8%, and 23.1% for group A, B, C, and D diagnostic groups from 2001 to 2002.¹⁵ Before the LAS, patients with COPD were more likely to undergo transplantation since they had a greater chance of surviving to transplant; however, after the initiation of the LAS, incorporating waitlist urgency into lung allocation, IPF has now become the most common indication for lung transplant.

2 The LAS has had a clear impact on waitlist outcomes in lung transplantation. The number of active waitlist patients declined by 54% since early listing no longer conferred an advantage. Waiting time to transplantation has decreased from 792 days in 2004 to 141 days in 2007. The median waitlist time in 2012 was 4 months with 65.3% of recipients transplanted within 1 year.²³ Mortality rates on the waiting list have decreased since implementation of the LAS but have started to increase recently to 15.4 per 100 waitlist years from 2010 to 2012, possibly due to an overall increase in the acuity and age of patients on the waiting list.²³ The median age of recipients has increased from 45 years in 1985 to 55 years after the institution of the LAS, with 27.2% of recipients older than 65 in 2012.^{4,22,23} According to a recent report, 20.7% of patients on the waiting list were older than 65 in 2012 compared with 2.5% in 2002 (Fig. 39-1).²³

An analysis of all transplant patients with COPD, IPF, and CF from 1992 to 1994 demonstrated a survival benefit for patients with IPF and CF but not with COPD.^{42,43} A similarly powered analysis of the European transplant experience demonstrated a survival benefit for all lung transplant groups.⁴⁴ Other studies have also called into question the transplant benefit for children with CF listed between 1992 and 2002.⁴⁵ Overall early survival (30-day and 1-year) has slowly improved since 1995, which has continued through the implementation of the LAS in 2005 with improvements in operative and postoperative care. A predictive model for posttransplant survival was also developed.¹⁰ When these models were applied to evaluate survival in 2,484 patients with these four primary diagnoses, factors including increasing recipient age, intensive care unit (ICU) admission, and the need for mechanical ventilation were significant predictors of 1-year mortality.

Other risk factors for earlier posttransplant mortality included donor/recipient BMI, recipient creatinine, bilirubin, and PA systolic pressure. Malnutrition increases morbidity and mortality after lung transplant. An albumin less than 3 g/dL has been correlated with an increased mortality at 1 year⁴⁶; 9% to 25% of lung transplant patients are malnourished. Allen et al.⁴⁷ found decreased survival in patients who were either under- or overweight.

Results of studies evaluating posttransplant survival after initiation of the LAS are conflicting. Since

the initiation of the LAS, sicker patients are being transplanted (Fig. 39-1), and an increasing LAS has been associated with a lower 1-year survival. Transplanted patients with an LAS score less than 35 had a 1-year survival of 85.7%, whereas those with an LAS score greater than 60 had a 1-year survival of 71.3%.⁴⁸ The median LAS continues to increase to 40.8 in 2011 with 6.3% of patients with LAS scores greater than 50 compared with a median LAS of 36.6 in 2005 with less than 2% greater than 50.⁴⁹ A study in 2008 showed an increased incidence of primary graft dysfunction and increased ICU stays after initiation of the LAS although the 1-year survival was similar.⁵⁰ McCue et al.⁵¹ reported no difference in posttransplant morbidity with a small statistically significant improvement in 1-year survival. One-year survival improved from 70% in 1988 to 1994 to 87% from 2007 to 2012.^{22,23} Thabut et al.⁵² evaluated the survival benefit of transplant patients with CF after initiation of the LAS and found that lung transplant decreased the risk of death by 69%, and a higher LAS was associated with an increased survival benefit.

Reevaluation and revision of the criteria that determine the LAS remains one of the objectives of the Thoracic Organ Transplantation Committee of the OPTN. Data will continue to be analyzed through large studies including REVEAL (Registry to Evaluate Early and Long-term Pulmonary Arterial Hypertension Disease Management) and the Lung Retrospective Data Collection Projects, and the LAS will continue to evolve to maximize the net lung transplant benefit.^{53,54} The first comprehensive revision of the LAS was approved in November 2012 by the OPTN Board of Directors but has yet to be implemented. The revision includes changes to the variables included in the LAS such as cardiac index, CVP, and serum creatinine and the weight given to each variable in the LAS calculation. These changes will have the greatest effect on patients in diagnosis group B.⁵³

Figure 39-1. Since the initiation of the Lung Allocation Score (LAS) in 2005, the percentage of waitlist patients older than 65 has markedly increased. Patients are also sicker with an increasing percentage of patients with an LAS score >50. Meanwhile, COPD (group A), with a lower waitlist mortality, has decreased as an indication for lung transplant while idiopathic pulmonary fibrosis (group D) has grown to become the most common indication. (Adapted from the 2012 OPTN/SRTR Annual Report.)

Critically Ill Patients

Before the institution of the LAS, critically ill patients were at a disadvantage because the primary criterion was time on the waiting list. Under the LAS, the risk of waitlist mortality carries a greater weight than posttransplant survival.¹⁰ A study by Russo et al.⁴⁹ evaluated associations between the LAS and postoperative morbidity and mortality. They found that an LAS of greater than 75 was correlated with a decreased 1-year survival and increased perioperative complications. There was no difference in mortality at 1 and 3 years. With the LAS, there has been some concern that the increased impact of predicted waitlist mortality will result in allocation of donor lungs to patients with a lower posttransplant survival. Russo et al.⁴⁹ found that patients with an LAS score between 90 and 100 had a survival rate of 1.56 years while those between 80 and 90 LAS had a survival of 2.28 years. A higher LAS score was also associated with primary graft dysfunction (PGD) and decreased graft survival.²² The rate at which the LAS changed over a patient's course affected survival with changes greater than five associated with a worse survival.⁵⁵

Extracorporeal Membrane Oxygenation

The use of ECMO can be lifesaving in cases of severe PGD posttransplant. Some centers prefer venoarterial ECMO in order to reduce blood flow to the donor lung thus limiting the degree of pulmonary edema⁵⁶ while others prefer venovenous ECMO due to the lower complication rate. ECMO is now available in more than 200 centers.^{57,58} Using ECMO as a bridge to lung transplant has been associated with poor outcomes in the past.⁵⁹⁻⁶¹ However, outcomes have improved with developments in oxygenator technology using polymethylpentene membranes to reduce plasma leakage, dual lumen cannulas and smaller pumps and oxygenators allowing ambulatory ECMO, centrifugal pumps, and

improvements in critical care.

In venovenous ECMO blood is drawn from the central venous system, passed through the pump and oxygenator, and returned to the right atrium. Newer dual lumen cannulas allow this to be performed through a single cannulation site, often using the jugular vein. Patients with high pulmonary arterial pressures and right heart failure may require conversion to venoarterial ECMO or an atrial septostomy. In venoarterial ECMO, blood is withdrawn from a central vein and returned to a peripheral or central artery providing hemodynamic and respiratory support. The configuration and cannulation depend on the patient's needs and mobility. Venovenous ECMO is a good choice in patients with hypercapnic or hypoxemic respiratory failure without significant right heart dysfunction, such as most patients with CF. A single dual lumen cannula with insertion in the jugular vein allows patients to ambulate. Physical therapy should be consulted as soon as possible. Ambulating patients require close coordination with the ECMO specialist, respiratory therapist, nursing, and the critical care team. Some patients can be extubated while on ECMO, with the goal to keep patients comfortable so they are able to participate in physical therapy. It is also important to avoid blood transfusions when possible to avoid development of antibodies that can limit donor organ availability, only transfusing patients when the hemoglobin is <6 g/dL, if there is hemodynamic instability, or if patients are hypoxemic despite ECMO support. For CO₂ clearance alone, a pumpless system driven by the patient's own arterial pressure can be used with groin cannulation, decreasing ventilator-induced trauma.^{62,63}

Venovenous ECMO may be insufficient for patients with significant right heart dysfunction and pulmonary hypertension. Venoarterial ECMO or pulmonary artery to left atrial cannulation may be more beneficial by unloading the right ventricle. Central cannulation is avoided when possible to prevent complicating the subsequent lung transplant. Femoral arterial cannulation makes ambulation more difficult and does not oxygenate the carotids and coronary arteries as well. Axillary arterial cannulation using a 6- to 8-mm vascular graft provides more effective upper body oxygenation.

3 Since the initiation of the LAS, patients on mechanical ventilation have higher scores and are more likely to undergo a transplant. These patients are also more likely to be deconditioned and have decreased posttransplant survival. In a study from 2010, patients undergoing transplant on mechanical ventilation had a significantly lower survival of 57% versus 70% at 1 year, although survival is similar after 6 months.⁶⁴ Ambulatory ECMO can be used to help prevent deconditioning of these patients prior to transplant.

The decision-making process must include a multidisciplinary team including the ECMO and critical care intensivist, transplant surgeon, pulmonologist, and social work. The goals of care include establishing adequate CO₂ removal, oxygenation, and circulatory support. Whether ECMO is being used as a bridge to recovery or to lung transplant should be established when possible before initiating ECMO. Factors to consider include the patient's age, the underlying pulmonary disease, social support, other organ dysfunction, the presence of infection, and variables affecting the potential waiting times including the patient's size and panel of reactive antibodies (PRA). Patients who have completed their transplant evaluation or are in the process of being evaluated, younger patients, and those who were listed prior to an acute exacerbation generally have better outcomes. Timing is important and the initiation of ECMO should not be delayed to the point where the patient is no longer a transplant candidate due to deconditioning. Their pulmonary disease should have progressed to the point where it is unlikely that they will improve, but patients must have sufficient functional reserve. Active bacteremia or highly resistant infections are contraindications. Patients with renal, hepatic, and cardiac failure are also not candidates for ECMO. It is important to carefully discuss the decision to proceed to ECMO with the patient and family, as well as considering the possibility of withdrawal from ECMO in the event that the patient is no longer a transplant candidate due to complications including sepsis, renal, liver, or left heart failure, stroke, or worsening functional status despite circulatory support. Daily clinical assessment is important to ensure that the patient continues to meet transplant criteria.

Due to the severity of pulmonary disease, patients with an LAS that is greater than 90 have a postoperative mortality that is higher than expected. In a study from 2005, ECMO was used as a bridge to transplant in 31 patients with 25 surviving to transplantation.⁶⁵ The 2-year survival rate was 74% in both the unsupported and the bridge to transplant groups. The rate of PGD was higher in the ECMO group.⁶⁵ In a study from 2013, 31 patients were successfully bridged to lung transplant, including 19 who were ambulatory, with an 80% 3-year survival.⁶⁶ In another study, 30 of 36 patients on ECMO were bridged to lung transplant with a 2-year survival rate of 60.5%. Survival was greater among patients with CF at 71% compared to idiopathic pulmonary fibrosis at 27.3%.⁶⁷ The duration of ECMO also affects morbidity and mortality. One study showed a 76% 1-year survival with patients on ECMO

less than 14 days having a significantly improved survival.⁶⁸ Fuehner et al. evaluated 26 patients bridged to lung transplant compared to 34 historical control patients on mechanical ventilation. Survival at 6 months was higher in the ECMO group at 80% versus 50%.⁶⁹ While transplant outcomes for patients undergoing ECMO as a bridge to transplant have been acceptable, larger cohort studies are needed to optimize selection criteria for patients bridged to transplant.

DONOR CONSIDERATIONS

Donor Selection

While the number of lung transplants has steadily increased, with 1,830 transplants in 2011, and waitlist times and waitlist death rates have decreased, the total number of patients on the waitlist has continued to increase to 2,200 highlighting the shortage of acceptable donors. The reasons that fewer lungs are available compared to other organs are multiple. Death from head injury or intracranial bleeding may lead to neurogenic pulmonary edema, while chest trauma can result in contusions or pneumothorax. All brain-dead donors are intubated and at risk for aspiration and nosocomial pneumonia, especially if there is a prolonged interval between hospitalization and declaration of brain death. In addition, hemodynamic instability, whether from herniation or trauma, often results in significant volume resuscitation that can contribute to acute lung injury. Criteria for an ideal lung donor include age <55 years, less than 20 pack-year smoking history, < 48 hours on the ventilator, a PaO₂:FiO₂ ratio >300, and no evidence of edema or infection (Table 39-5).^{70,71}

Bronchoscopy allows for direct examination of the bronchial tree and for microbiologic examination of the bronchoalveolar lavage (BAL), the results of which may influence later treatment of the recipient. Chest radiography and computed tomography are useful to evaluate for effusions, pulmonary infiltrates, consolidation, and contusions that could contribute to donor hypoxemia. Unlike other solid organ transplants, lungs are unique in carrying a relatively high risk of infection (i.e., pneumonia) following transplant. Because all brain-dead patients have endotracheal tubes and are on mechanical ventilation, there is a high likelihood that the airway is either colonized with bacteria or that there is ongoing pulmonary infection.

Not infrequently, the donor lungs may not be suitable because of infiltrates when all other organs are acceptable. Significant infiltrates typically preclude the use of donor lungs. However, a bilateral lung transplant may still be considered, in a recipient with a higher LAS, when there is a small infiltrate in one lung without evidence of purulent secretions and the contralateral lung appears normal. In addition, unilateral pulmonary infiltrates do not necessarily preclude use of the normal contralateral lung for a single lung transplant.⁷²

Aspiration at the time of the initial insult resulting in brain death is a common cause of pulmonary infiltrates in potential donors. Signs of aspiration may not be evident on a chest radiograph for 24 to 48 hours, underscoring the importance of the bronchoscopic examination. Characteristic early bronchoscopic evidence of aspiration includes erythematous tracheobronchial mucosa, purulent secretions, and occasionally the presence of food particles.

Table 39-5 Criteria for Ideal Lung Donors

Age <55 years
ABO compatibility
Height match within 20% of recipient
Clear chest radiograph
PaO ₂ >300 on FiO ₂ of 1.0, PEEP 5 cm H ₂ O
Tobacco history of <20 pack-years
Absence of chest trauma
No evidence of aspiration or pulmonary sepsis
No previous cardiothoracic surgery
Negative sputum Gram stain
Absence of purulent secretions

PEEP, positive end-expiratory pressure.

Major pulmonary contusion resulting from blunt chest trauma may also eliminate lungs from donor consideration, but minor to moderate unilateral contusions are often acceptable. Evaluating the full

extent of the contusions at the time of donor procurement can be difficult because the interval from injury to determination of brain death and donation may be short. Although the detrimental effect on gas exchange caused by a pulmonary contusion is usually transient, further bleeding into the lung parenchyma could occur if cardiopulmonary bypass is required to perform the transplant. Pulmonary edema may occur as a result of massive head injury and may be exacerbated by donor management protocols directed at maintaining satisfactory perfusion and function of nonpulmonary organs.

The limitation in overall donor organ availability is further compounded by the relatively smaller number of usable donor lungs. The standard criteria for an acceptable donor lung are particularly stringent ([Table 39-5](#)).⁷³ There are limited data available to validate these criteria, and multiple single-institution retrospective reports evaluating “extended criteria” donors have shown conflicting short- and long-term outcomes for almost every criterion. Clinically, these selection criteria provide an overall indication of the quality of the donor lungs. When multiple criteria are not met, the risks of transplanting such lungs likely outweigh the benefits. However, if one aspect of the donor lungs is marginal, the lungs may still be acceptable, and the risks must be weighed against recipient acuity and the likelihood of receiving another offer, taking the patient’s size and antigenic status into account.

There are several caveats that have come into “standard” practice. Although leukocytes or occasional bacteria on sputum Gram stain can be acceptable, the presence of gross pus or fungal elements confers a high risk of perioperative complications.⁷⁴ In the annual report of lung transplant outcomes, increasing donor age modestly increased the risk of 5-year mortality.¹⁶ Analysis of a large cohort of more than 750 lung and heart–lung recipients demonstrated significantly worse long-term survival with ischemic times greater than 330 minutes. Hazard ratios for death were threefold higher in patients with ischemic times of 8 hours and nearly eightfold higher when ischemia reached 10 hours.⁷⁵ The detrimental effects of older donor age and longer ischemic times appear to be additive.⁷⁶

Donor Management

4 Despite the inability to identify “extended” donor criteria that reliably provide acceptable grafts, donor management optimization has allowed an increase in donor recovery and is likely responsible for the increase in the overall number of transplants performed over the last decade. The number of donor lungs recovered has increased from 0.25 lungs per donor in 2000 to 0.39 lungs per donor in 2012.²³ [Algorithm 39-1](#) outlines the donor management algorithm used at the University of Michigan. Key principles include the early use of steroids and thyroxine to prevent neurogenic pulmonary edema and to maintain cardiovascular stability, aggressive alveolar recruitment with positive end-expiratory pressure (PEEP) for patients with a partial pressure of arterial oxygen (PaO₂) less than 350 mm Hg, optimization of intravascular volume, maneuvers to prevent aspiration, and lung-protective ventilation utilizing high frequency, low tidal volumes, and PEEP to prevent volutrauma and barotrauma to the lungs. Using these maneuvers has been shown to double the organ recovery rate without detrimental effects on 30-day or 1-year survival.⁷⁷

Investigators at the Texas Organ Sharing Alliance identified 330 potential lung donors over a 4-year period preceding initiation of an active donor management protocol and 381 potential donors managed on the protocol in the subsequent 4 years.⁷⁷ Overall, 1.7 organs per donor were procured in 19% (136/711) of potential donors. Prior to initiation of the management protocol, organ procurement occurred in only 12% (38/330), recovering 1.6 lungs per donor. In contrast, with lung-protective donor management, organ procurement occurred in 26% (98/381), recovering 1.7 organs per donor.

Algorithm 39-1. The donor management algorithm used at the University of Michigan in coordination with the organ procurement organization, Gift of Life. Optimal PEEP is determined by increasing PEEP 2 cm of H₂O every 3 to 5 minutes until compliance decreases. Recruitment maneuvers include CPAP at 30 cm of H₂O for 30 seconds every 20 minutes × 3. P/F, PaO₂/FiO₂; IBW, ideal body weight; TV, tidal volume; APRV, airway pressure release ventilation; CPAP, continuous positive airway pressure.

Following initial organ acceptance, the lungs might be declined if the procurement team identifies significant purulent secretions during bronchoscopy, if arterial blood gases deteriorate significantly to a P/F ratio <300 or if the donor lungs are found to have poor compliance. On-site measurement of selective pulmonary vein blood gases at the time of donor procurement can aid the procuring team in determining whether donor hypoxemia is due to unilateral or bilateral lung compromise.⁷⁸ Size of the donor lungs is less important when the recipient suffers from emphysema, in which each hemithorax is large, compared to pulmonary fibrosis, in which the hemithorax can be significantly contracted. The most important size consideration is a reasonable match between donor and recipient height.

Lung Preservation

Unlike the kidney, liver, or pancreas, immediate acceptable function of the transplanted lung is vital for survival of the recipient. PGD occurs in 10% to 25% of cases and is the most common cause of 30-day mortality after lung transplantation. PGD is associated with higher rates of chronic rejection (bronchiolitis obliterans syndrome [BOS]) and correlates with increased 1- and 5-year mortality.⁷⁹

5 Ischemia-reperfusion injury refers to the cellular and architectural changes that occur after cross-clamp of the donor aorta to release of the recipient pulmonary arterial clamp (ischemic phase) through the immediate restoration of systemic gas exchange (reperfusion phase). Minimizing ischemia-reperfusion injury is crucial to ensuring good early graft function. Advances in donor lung preservation techniques have led to more consistent quality of the donor allograft and lower rates of PGD.

Current preservation techniques depend on cold static preservation to decrease metabolic activity using topical cooling and cold pulmonary perfusion. A major development in lung preservation has been the widespread clinical use of a preservation solution specifically designed for lung procurement. Traditional preservation solutions such as Euro-Collins solution were designed to maintain intracellular ion balance and cell wall integrity. Low-potassium dextran (Perfadex, Vitrolife, Goteborg, Sweden) has

an extracellular fluid ion balance and has been shown to have beneficial effects on endothelial cell function and pulmonary microcirculation. Five single-institution reports have demonstrated significantly better initial lung function with low-potassium dextran, while one study showed no difference.⁸⁰

The donor allograft is cooled to minimize cellular metabolism while maintaining vital cellular function. Although small animal studies have demonstrated better postischemic function at preservation temperatures between 15°C and 23°C, practical limits have led to the common practice of cooling to 4°C to 8°C (the temperature of ice water). Other techniques that have traditionally been employed to ensure rapid homogeneous cooling of the lung include topical cooling, antegrade flush through the pulmonary artery, and techniques to maintain patency of the microcirculation including the administration of prostaglandins prior to cross-clamp and the maintenance of ventilation after cross-clamp. Retrograde flush through the pulmonary veins purges the pulmonary and bronchial circulations, has a more homogeneous distribution, and can evacuate pulmonary arterial clots or fat emboli. Clinically, retrograde perfusion in combination with the antegrade flush has been shown to improve immediate posttransplant oxygenation.⁸¹

Optimal storage techniques have also evolved. After flushing of the pulmonary circulation, the lungs are recruited to expand atelectatic areas, and the trachea is stapled and divided prior to separation from the donor and storage for transport. Methods of lung recruitment have been studied in animal models and have shown that ventilation with less than 50% oxygen and maintenance of airway pressure between 15 and 20 cm H₂O have beneficial effects on capillary leak, lipid peroxidation, and barotrauma.^{82–84}

Lung injury likely results not only from the ischemic insult but also from reperfusion of the ischemic lung. Several experimental models of acute lung injury implicate oxygen free radicals as a factor in reperfusion injury. A significant early increase in lung permeability is seen after an ischemic period followed by reperfusion, which improves within several hours. After single lung transplantation, changes in the contralateral, nonischemic lung are presumably the result of substances released during reperfusion of the ischemic lung. Animal models have demonstrated that gradual pressure-controlled reintroduction of blood flow and a protective ventilation strategy of high frequency and low tidal volume reduce lung injury.^{85,86}

Expanding the Donor Pool

Ex Vivo Lung Perfusion

Currently only 20% of brain death donor lungs are used for transplantation due to damage from trauma or complications related to brain death and critical care including barotrauma and edema.^{87,88} The number of patients on the waiting list exceeds the number of donor lungs available. With current cold static preservation techniques, it is difficult to assess lung function after organ procurement. Normothermic ex vivo lung perfusion (EVLP) (Fig. 39-2) allows for objective evaluation of marginal lungs in an optimized environment leading to improved utilization of available donor lungs.

Early attempts at EVLP failed due to the development of pulmonary edema.⁸⁹ Steen et al.⁹⁰ initially evaluated EVLP as a means to evaluate donor lungs from uncontrolled donation after cardiac death (DCD) circumstances. They developed an optimized colloid lung perfusate solution that keeps fluid within the intravascular space and also provides nutrition during lung perfusion (Steen Solution, XVIVO, Sweden).⁹¹ The perfusion period was initially short, at around 60 minutes, and the solution was mixed with red blood cells. The Toronto group first described stable long-term perfusion for 12 hours using an acellular Steen solution, protective perfusion with only 40% of the cardiac output, and physiologic left atrial positive pressure.⁹²

Lung injury is reflected in the development of pulmonary edema during EVLP. Parameters used to evaluate the donor lungs include the perfusate pO₂, airway pressure, lung compliance, and pulmonary vascular resistance. While PaO₂ is one of the most important *in vivo* donor parameters, pO₂ is less useful *ex vivo*. Dynamic compliance is the most sensitive parameter for the development of pulmonary edema *ex vivo*.⁹³ Parameters are monitored over a 3- to 4-hour period, and it is important to take the trends into account in addition to the absolute values. A delta pO₂ (pulmonary vein pO₂ – pulmonary artery pO₂) of greater than 300 mm Hg on 100% is used as criteria for lung acceptance for transplantation. Chest x-rays, bronchoscopies, and deflation tests are also performed.

Figure 39-2. The donor lungs have been placed on ex vivo lung perfusion with pulmonary arterial and left atrial cannulation and the change in pO_2 , compliance, and pulmonary vascular resistance will be evaluated to determine if the lungs are acceptable for transplantation.

Several prospective trials have recently been completed or are underway including the NOVEL trial (United States; XVIVO), the HELP trial (Toronto; XVIVO), the INSPIRE and EXPAND trials (Europe and the United States; Transmedics), the Perfusix trial (United States; Perfusix), the Vienna trial (Vienna; XVIVO), and the DEVELOP trial (United Kingdom; Vivoline). Different technologies and techniques are used in the various trials. While the NOVEL, HELP, DEVELOP, EXPAND, and Perfusix trials are evaluating extended criteria lungs, the INSPIRE and Vienna trials are evaluating standard criteria lungs. In the HELP trial, 80% of the lungs from brain dead and DCD donors that were not initially acceptable for transplantation were transplanted after EVLP with outcomes equivalent to standard controls.^{94,95} The incidence of PGD grade 3, airway complications, and the need for ECMO has been <5%.

EVLP also provides the potential for rehabilitating injured lungs. Specific therapies could be used depending on the type of lung injury. Terbutaline increases clearance of alveolar fluid during EVLP⁹⁶ while applying surfactant to porcine lungs injured by aspiration improved graft function.⁹⁷ Treatment of donor lungs with high-dose antibiotics could also be useful with the large number of lungs rejected for pneumonia.^{98,99} For donors with acute pulmonary emboli, tissue plasminogen activator has been used to lyse emboli with good outcomes after transplant.¹⁰⁰ Gene therapy with IL-10 is also being studied using adenoviral vectors in rejected donor lungs and has shown improved function.¹⁰¹ In addition, the application of stem cells has been reported to restore endothelial barrier permeability after lung injury.¹⁰²

Donation after Cardiac Death

DCD may be valuable in increasing the donor pool with only 20% of donor lungs acceptable for transplant. The lung is unique compared to other organs since it does not depend solely on perfusion for oxygen, and cell viability can be maintained by mechanical ventilation after cardiac arrest. Cadaveric lungs have been shown experimentally to remain viable for 1 hour to 90 minutes after arrest with function declining after 2 hours although this does not account for the agonal phase, which can vary in duration and the degree of hypoxia and hypotension.^{103–105} On the other hand, DCD donor lungs may actually have better function, since they are not exposed to the catecholamine surge and neurogenic pulmonary edema associated with brain death and may be less sensitive to ischemia-reperfusion injury.¹⁰⁶ The Toronto group reported that lungs from brain-dead donors had higher levels of proinflammatory cytokines than DCD lungs.¹⁰⁷

Currently only 2% of DCD lungs are utilized in the United States.¹⁰⁸ However 13.3% of lung transplants in the United Kingdom and 22.5% in Canada are from DCD donors.¹⁰⁹ DCD donors are classified using the Maastricht classification into four groups: I, dead on arrival; II, failed resuscitation; III, awaiting cardiac arrest; IV, cardiac arrest in a brain-dead donor.¹¹⁰ Controlled DCD (category III and IV) is the approach of choice and includes withdrawal of life support in the ICU or operating room so the organs can be allocated in advance with the ability to evaluate graft function and discuss donation with the family. DCD donors generally have an irreversible cerebral injury, high spinal cord injury, or end-stage muscular disorder and are expected to die within 1 hour of the withdrawal of support. Predictive models have been developed to predict the potential for expiration based on the need for pressors, cardiopulmonary status, age, BMI, Glasgow Coma Scale, peak and inspiratory pressures, and the PaO_2/FiO_2 ratio.^{111–113}

Death of the donor, with irreversible cessation of respiration and circulation, must be declared before organ retrieval can begin, and the retrieval process must not alter or hasten death. One of the main

differences from brain death donation is the addition of a warm ischemia period. The length of the agonal phase, from the withdrawal of care until the declaration of death which includes a 2- to 5-minute no touch period after circulatory arrest, varies among donors and is associated with impaired graft function and longer hospital stays.^{114,115} Most DCD protocols limit the agonal phase to 60 minutes for lung donation. Heparin is generally given before cardiac arrest although some donor hospitals restrict its use since heparin can hasten death in donors with intracranial hemorrhage. Heparin given postarrest can prevent pulmonary thromboemboli, and retrograde perfusion is helpful in clearing any emboli^{116,117} with no difference in thrombus formation.^{118–121} After arrest, the donor lungs can be rapidly cooled topically, through chest tubes or after exposure of the lungs, followed by antegrade perfusion with cold Perfadex and retrograde perfusion through the pulmonary veins.

EVLP may increase the use of DCD lungs by allowing evaluation after cardiac death in optimized conditions, which is especially useful in DCD cases since in vivo evaluation is more limited and the warm ischemia time is variable. There is also the potential to improve lung function. The Toronto group transplanted lungs using 20 donor lungs placed on EVLP, including 9 DCD lungs, with no significant difference in 30-day mortality, ICU or hospital length of stay. Although the use of EVLP remains controversial since DCD lung transplants can also be performed with good outcomes without EVLP.^{108,109}

The first successful lung transplant from a DCD donor was reported in 1995.¹²² Early and midterm outcomes after transplantation of lungs from controlled DCD donors are comparable to standard lung transplantation.^{123–125} Although the incidence of PGD grade 3 was not significantly different, in some series there was a trend toward increased early graft dysfunction with improvement within 72 hours and more frequent ECMO usage.^{125,126} The incidence of BOS is similar but was more frequent in the brain death group at 1 year in a series from the Netherlands.¹²⁷ In a series of uncontrolled DCDs from Madrid, the incidence of BOS at 5 years was 45%, which was significantly higher, although outcomes were improved after using EVLP to evaluate donor lung function.¹²⁸

TRANSPLANTATION OPERATION

Single Versus Bilateral Lung Transplant

Over the past decade the ratio of bilateral lung transplants has continued to increase from 49.9% of all lung transplants in 2002 to 67.3% in 2012.²³ Bilateral lung transplant is required for septic lung diseases, including CF, due to the risk of contaminating the transplanted lung. Whether to perform a single or bilateral lung transplant for other diseases remains controversial, and short- and long-term outcomes as well as benefits to society should be considered.^{129,130} While double lung transplants may provide greater benefits to the recipient, single lung transplants may maximize the benefit to society by allowing two patients to be transplanted.

The decision to proceed with single or bilateral lung transplantation depends on several factors including the primary diagnosis, the presence of pulmonary hypertension, recipient age, and donor lung availability. Patients with chronic infection, such as those with CF or immunoglobulin deficiency disorders, require bilateral transplant. Single lung transplantation can be considered for patients with restrictive physiology (pulmonary fibrosis), particularly if there is no evidence of secondary pulmonary hypertension. The decision on which side to transplant is based on both donor lung availability and the recipient's quantitative ventilation perfusion scan.

In patients with end-stage obstructive lung disease, specifically emphysema, there was concern initially that single lung transplantation would be associated with altered physiology due to hyperventilation of the overly compliant native lung and that mediastinal shift would result in significant ventilation and perfusion mismatch and compromised function of the transplanted lung. It has been demonstrated that single lung transplantation is acceptable in patients with emphysema,¹³¹ especially for older patients, with significant improvements in mean 6-minute walk results (Fig. 39-3). However, bilateral lung transplant recipients appear to have greater improvement in FEV₁ at 3-month (Fig. 39-4) and 1-year follow-up.¹³²

A single lung transplant is simpler technically and avoids a sternotomy. While some studies have found improved early 30-day and 3-month survival with single lung transplant,^{133,134} others have found no difference in survival^{135,136} or other postoperative outcomes including mechanical ventilation and ICU stay.^{137,138} Bilateral lung transplantation, when indicated, has been simplified by the development and refinement of the sequential rather than the *en bloc* double lung technique, which required a

tracheal anastomosis with cardiopulmonary bypass and resulted in significant perioperative morbidity and mortality.¹³⁹ Bilateral sequential lung transplant can be approached either by median sternotomy or bilateral thoracotomies using cardiopulmonary bypass when necessary depending on the degree of pulmonary hypertension and impairment in gas exchange. A bilateral thoracosternotomy (“clamshell”) incision permits easier exposure of the hilum especially on the left but tends to be more painful.

Figure 39-3. Mean 6-minute walk results for patients undergoing single lung transplantation for emphysema. There is significant improvement at 6 weeks with continued improvement after 12 weeks.

Figure 39-4. Comparison of the percent predicted forced expiratory volume in 1 second (FEV1) in 14 patients undergoing single and 10 patients undergoing bilateral pulmonary transplantation for chronic obstructive pulmonary disease.

In patients with pulmonary hypertension, single lung transplantation historically had been felt to be adequate to unload the right ventricle by reducing pulmonary artery pressures leading to improved right ventricular function. Although no significant survival benefit has been demonstrated between patients receiving single, bilateral, or heart–lung transplantation, most patients undergo bilateral sequential transplantation unless there is evidence for inotrope-dependent left ventricular heart failure.¹⁴⁰ Patients with pulmonary arterial hypertension listed for lung transplantation tend to be younger, and thus may be more likely to obtain more durable improvement in lung function following bilateral lung transplantation. In addition, perioperative management and improved hemodynamic performance appear to be facilitated by bilateral rather than single lung transplantation. Although seemingly contradictory, bilateral lung transplantation for this population also might improve organ utilization, since marginal bilateral lungs are likely more readily available than an “ideal” single donor lung.

Bilateral lung transplant results in greater improvements in spirometry.^{129,141} A study by Anyanwu et al. shows that over 3 years, quality of life was improved to a greater degree after bilateral versus single lung transplant while Gerbase et al. found no significant difference in quality of life.¹²⁹ Meyer et al.¹³⁶ evaluated 2,260 patients undergoing lung transplant for COPD in the United Network for Organ Sharing (UNOS) database and found that long-term survival was better following bilateral lung transplant for recipients less than 60. Thabut et al.¹⁴² evaluated 9,883 patients with COPD and found that median survival was longer after bilateral transplant but not for patients older than 60. Nwakanma¹⁴³ also found no significant difference in long-term survival in 1,656 patients older than 60.

In a study of 821 patients with IPF, there was no significant difference in survival between single and bilateral lung transplants with a trend favoring single lung transplant.¹³³ Force et al. evaluated 3,860 patients with IPF in the UNOS database and found no survival advantage on multivariate analysis, but the 1-year survival for those living at least 1 year was greater after bilateral transplant. Risk factors for early mortality included recipient age greater than 57 and donor age greater than 36.¹⁴⁴ The authors concluded that bilateral transplant should be considered for younger patients with IPF. Patients undergoing bilateral transplant from 1994 to 2011 had a greater median survival compared to single

lung transplants (6.9 vs. 4.6 years).¹⁴⁵

Bilateral transplant has also been found to have a survival benefit in sicker patients with a higher LAS with a 14.4% lower 1-year mortality after a bilateral transplant.¹⁴⁶ Black et al.¹⁴⁷ evaluated 8,778 patients in the UNOS database and found that in patients with an LAS >75, the 1-year survival was significantly lower in patients undergoing a single lung transplant. While several smaller studies have found an increased risk of BOS after single lung transplant,^{129,130,148} Meyer et al.,¹³⁶ found no difference in the risk of BOS in 2,260 patients with COPD in the UNOS database at 3-year follow-up.

While no randomized or prospective, controlled studies have been performed, the ratio of bilateral lung transplants has continued to increase over the past decade. Based on the available data, our approach has been to perform bilateral lung transplants in most patients younger than 60 while a single lung transplant is performed in older patients with IPF or COPD especially if pulmonary pressures are only mildly elevated and there is a significant difference in perfusion between the two lungs.

OPERATIVE TECHNIQUE

Single Lung Transplantation

In the recipient operation, a standard fourth intercostal space posterolateral thoracotomy is performed. In patients with emphysematous disease, a muscle-sparing axillary thoracotomy can be performed, but this approach might not afford suitable exposure for patients who have significant volume loss due to severe pulmonary fibrosis, a previous thoracotomy, or pleurodesis. The groin should always be included in the sterile field. If necessary, cardiopulmonary bypass can be performed by cannulating the femoral vessels in the groin or the right atrium and ascending aorta either through a right thoracotomy or a clamshell incision. The hilar dissection (Fig. 39-5) differs from that of a pneumonectomy in that the main pulmonary artery should be mobilized and divided distal to the origin of the first segmental trunk, and the pulmonary veins should be divided at the main segmental tributaries as they return to the superior or inferior veins. Care should be taken to preserve the peribronchial lymphatic and areolar tissue in order to maintain the vascular supply of the mainstem bronchus just proximal to the origin of the upper lobe bronchus. In addition, injury to the phrenic nerve must be avoided, especially in the setting of pleural adhesions from previous surgery, severe emphysema, or pulmonary fibrosis, to avoid diaphragmatic dysfunction, which can adversely affect posttransplant functional recovery.

The donor lung is prepared by dissecting the left atrial cuff and the proximal pulmonary artery from the surrounding tissues. Retrograde perfusion is then administered by perfusing the superior and inferior pulmonary veins with cold Perfadex while the lung is still inflated. The bronchial cuff is prepared by transecting the mainstem bronchus approximately two cartilaginous rings from the orifice of the upper lobe bronchus to maximize retrograde perfusion to the bronchial anastomosis.

Implantation of the donor lung begins with the anastomosis between the donor and recipient bronchus. An end-to-end anastomosis is performed with a running 4-0 polydioxanone suture on the membranous airway and figure-of-eight 4-0 polydioxanone sutures to reapproximate the cartilaginous airway.^{149,150} Absorbable sutures are used rather than polypropylene to reduce the risk of suture granuloma formation. The peribronchial areolar and lymphatic tissue can be reapproximated between the donor and recipient, particularly anteriorly, in order to separate the bronchial and pulmonary arterial anastomoses. Advocates of bronchial arterial revascularization with a native internal mammary artery have reported decreased bronchial anastomotic complications in small series, but this technique has not received widespread acceptance due to the increased complexity and ischemic times.¹⁵¹⁻¹⁵³

Figure 39-5. Mobilization of the hilum of the right lung. The pulmonary artery is encircled, and the first branch is ligated and divided. The superior and inferior pulmonary veins have been exposed. Both the artery and veins are taken as close to the lung as possible. The bronchus is divided at the level of the takeoff of the upper lobe to minimize ischemia of the airway.

The vascular anastomoses are then performed sequentially using running 4–0 or 5–0 nonabsorbable polypropylene sutures. Our preference has been to first perform the left atrial anastomosis followed by the pulmonary arterial anastomosis. The pericardium is opened around the left atrial cuff allowing the left atrium to be clamped centrally to the branch point of the superior and inferior veins. The recipient pulmonary vein stumps are prepared by unifocalization into one left atrial cuff to reduce the risk of pulmonary venous obstruction. In constructing the pulmonary arterial anastomosis, care must be taken to trim the donor pulmonary artery to the appropriate length to avoid kinking of the low-pressure vessel. Once the vascular anastomoses are completed, the lungs are gently ventilated as the vessels are deaired with the patient in the Trendelenburg position, first removing the pulmonary arterial clamp followed by the left atrial clamp prior to tying the anastomotic sutures. The chest is closed in standard fashion.

Bilateral Lung Transplantation

The technique of double lung transplantation has evolved considerably since the late 1980s from an *en bloc* technique to a bilateral, sequential technique.^{139,154} With the patient in the supine position, this operation can be performed through a median sternotomy, bilateral thoracosternotomy (clamshell) incision (Fig. 39-6), bilateral anterior thoracotomies without sternal division, or bilateral muscle-sparing axillary thoracotomies. The bilateral thoracosternotomy incision provides the widest exposure facilitating dissection and mobilization of the hilar structures as well as cannulation of the right atrium and ascending aorta if cardiopulmonary bypass is necessary. This exposure is particularly important in recipients with diffuse dense pleural adhesions as is often seen in patients with chronic infections with bronchiectasis or CF, previous pleurodesis, or with severe apical adhesions after lung volume reduction in patients with emphysema.

Figure 39-6. Patient positioning for a bilateral, sequential lung transplant. Bilateral anterior thoracotomies are made in the fourth intercostal space with a transverse sternotomy when needed for exposure (clamshell incision).

Although both lungs are replaced, the operation can often be performed without cardiopulmonary bypass unless the recipient has significant pulmonary hypertension or severely limited gas exchange. By replacing the lung with the least function first, based on the quantitative ventilation perfusion scan, oxygenation and ventilation can be maintained by the native lung. If the patient is unable to tolerate single lung ventilation due to inadequate gas exchange or worsening right ventricular dysfunction with increasing pulmonary hypertension (near or suprasystemic), then cardiopulmonary bypass is initiated. If recipient hemodynamics are significantly impaired during retraction and exposure of the left atrial anastomosis, particularly during left lung recipient pneumonectomy and implantation, opening the recipient pericardium can be sufficient to permit safe manual cardiac retraction or application of an apical cardiac stabilizer.¹⁵⁵ In patients with severe mediastinal shift due to volume loss from pulmonary fibrosis, cardiopulmonary bypass may be necessary to provide sufficient cardiac decompression in order to obtain adequate exposure to complete the anastomoses.

The donor lungs are prepared leaving a cuff of left atrium around the pulmonary veins on each side. The recipient pneumonectomy is performed one side at a time with the patient maintained using single lung ventilation of the contralateral lung. Each donor lung is implanted using the same technique as described for single lung transplantation. The bronchial anastomosis is completed first, followed by the left atrial and pulmonary arterial anastomoses. Once perfusion and ventilation are restored to the first implanted lung, this lung then supports the patient while the remaining lung is removed and the second lung is implanted.

RESULTS

1. Based on OPTN data, 27,043 lung transplants were performed between 1988 and 2013. In 2012, 52.5% of transplanted patients were from diagnosis group D, including pulmonary fibrosis, which is now the most common indication for lung transplant (Fig. 39-1).²³ LAS scores continue to increase with 12.7% of transplant candidates with an LAS of 50 to 100 in 2006 compared to 22.5% in 2012. Of those patients listed, only 2% were listed for a heart–lung transplant. In 2012, 1,783 lung transplants were performed with 68% bilateral transplants and 5.5% retransplants. By the end of the first year after transplantation, approximately 80% of recipients report no limitations in activity.

6 Overall, survival after transplant has steadily improved with time. Between 1988 and 1994, median survival was 3.9 years while the median survival in 2012 was 5.3 years.²³ For patients who survived at least 1 year, the survival was 6.7 years. In this most recent era of lung transplant, the overall 1-year

survival rate following lung transplant was 81.4% and the 5-year survival was 53.5%. Patients receiving bilateral lung transplant survive significantly longer than patients after single lung transplant (median survival of 6.2 vs. 4.5; $p < 0.0001$). In general, younger recipients have a longer survival than older patients. Patients with CF have the best median survival (6.4 years) as they comprise a younger population and in general will receive two lungs secondary to their infectious lung disease. Median survival for patients with pulmonary fibrosis is significantly lower at 4.1 years, and that of patients with COPD is 5 years.

For all recipients, the factors associated with the highest risk of 1-year mortality were the era in which patients were transplanted, intravenous inotropes, and mechanical ventilation. The most significant risk factor for 5-year mortality was the development of BOS within the first year of transplant.¹⁶

IMMUNOSUPPRESSION

Immunosuppression is initiated in the immediate perioperative period and continued for the remainder of the recipient's life. Regimens typically include a calcineurin inhibitor, either cyclosporine or tacrolimus; a purine synthesis antagonist, either azathioprine or mycophenolate mofetil; and a corticosteroid, either methylprednisolone (intravenous) or prednisone (oral). In an open-label randomized trial of 90 patients who received either cyclosporine or tacrolimus,¹⁵⁶ subjects who were treated with tacrolimus experienced significantly less acute rejection. Lymphocytic bronchitis was also less frequent among patients receiving tacrolimus. In addition, fewer patients developed stage 0-p BOS (not statistically significant). The investigators used a composite endpoint including cumulative acute rejection score, cumulative lymphocytic bronchitis score, or the development of BOS stage 0-p (10% or greater decrease in FEV₁). No difference in graft survival was seen. Although diabetes was slightly more prevalent among subjects treated with tacrolimus, there were no differences observed between the two treatment groups in terms of hypertension, chronic renal disease, posttransplant malignancy, or total number of infections. In 2012, more than 90% of lung transplant recipients were treated with tacrolimus.²³ Rapamycin (sirolimus) is a serine/threonine kinase inhibitor that can be used as a second-line agent for treatment of acute rejection, sometimes in combination with calcineurin inhibitors, but such use is considered off-label and not recommended. In addition, rapamycin is absolutely contraindicated in the early posttransplantation period because of an association with fatal bronchial anastomotic dehiscence.

In other solid organs, use of induction (perioperative) antithymocyte regimens appears to be beneficial in reducing both acute and chronic rejection. There are limited data supporting the use of such agents in lung transplantation. In a study of 44 patients randomized to conventional triple-drug immunosuppression with or without rabbit antithymocyte globulin, a significant reduction in early acute rejection from 41% to 5% was observed with the use of rabbit antithymocyte globulin, but there was no apparent effect on the total number of rejection episodes. Compared to induction immunosuppression, the time to onset of BOS was earlier and graft survival was worse with conventional therapy alone, but these differences were not statistically significant. Several studies comparing antithymocyte globulin with T-cell-specific interleukin-2 (IL-2) receptor (CD25) monoclonal antibody suggest that outcomes, including early acute rejection and freedom from rejection, are equivalent¹⁵⁷ if not worse^{158,159} for patients treated with IL-2 receptor antibody. Treatment-related complications, particularly cytomegalovirus infection, appear to be equivalent for these induction agents. These studies do not provide sufficient evidence, and lack sufficient power, to determine whether their use is beneficial for the prevention of acute or chronic rejection. However, the use of induction therapy has increased from 23% in 1998 to 55% in 2012 with IL-2 receptor antagonists being the most commonly used agents.²³

COMPLICATIONS

Complications after pulmonary transplantation occur frequently, may be severe, and occasionally result in death (Table 39-6). Compared to other solid organ transplants, lung recipients have the highest rates of rehospitalizations for complications at 43.7 per 100 patients.²³ Intraoperative complications include technical problems with the vascular or bronchial anastomoses, injury to the phrenic or recurrent laryngeal nerves, and myocardial infarction. Early postoperative complications include PGD, infection, and problems with airway healing and acute rejection. The most common late complications are

infection and bronchiolitis obliterans (chronic rejection). Intra-abdominal complications are not uncommon while wound infection occurs rarely. Two important issues regarding standard immunosuppressive therapy are the various side effects associated with these agents and their interactions with other commonly prescribed medications.¹⁶⁰ Despite the progress made in operative techniques and early postoperative care, noninfectious, nonpulmonary complications related to long-term immunosuppression remain common. Five years after transplant, 66.7% of patients have hypertension, 53.8% hyperlipidemia, 49.8% renal dysfunction, 42.5% diabetes, and 18.3% have developed a malignancy with the risk of cancer three- to fourfold higher in patients after transplant.^{23,161}

Table 39-6 Complications

Short Term
Bleeding
Airway complications (dehiscence)
Kinking of the pulmonary artery
Venous outflow obstruction
Primary graft dysfunction
Infection
Pleural space complications (pneumothorax, effusion, empyema)
Acute rejection
Long Term
Infection
Airway complications (stenosis, granulation, malacia)
Malignancy (posttransplant lymphoproliferative disorder, skin cancers)
Chronic rejection/bronchiolitis obliterans

Causes of recipient death can be categorized according to the time frame in which they occur. Early deaths (less than 30 days following transplant) most commonly result from primary graft failure (28.2%).¹⁶ Infection is the second most common cause of early death (20.3%), followed by heart failure (11.1%). Rejection accounts for 4.3% of deaths in the early posttransplantation period. Hemorrhage and airway dehiscence each are responsible for 8.3% of early postoperative deaths. Infection accounts for about 39.5% of deaths within the first year of transplant (after 90 days). About one-third of deaths result from manifestations of chronic rejection and obliterative bronchiolitis, the single most significant barrier to long-term survival following lung transplantation. Respiratory failure and malignancy are the next most common causes of late mortality.

Primary Graft Dysfunction

Mild, transient pulmonary edema is common in the freshly transplanted allograft. In approximately 15% of cases, the injury is sufficiently severe to cause PGD. While ischemia-reperfusion injury is the likely cause, surgical trauma and lymphatic disruption may also be contributing factors. The diagnosis rests on the presence of widespread infiltrates on chest radiographs, severe hypoxemia within 72 hours after transplantation, and the exclusion of other causes of graft dysfunction, such as volume overload, pneumonia, rejection, occlusion of the venous anastomosis, and aspiration. Treatment is supportive relying principally on conventional mechanical ventilation. Independent lung ventilation, inhaled nitric oxide, and ECMO have been used as adjunctive measures. Mortality rates of up to 60% have been reported, and among those who survive, the recovery period is often prolonged, but achievement of normal allograft function is possible. The results of emergency retransplantation in such cases have been poor.^{160,162,163}

The impact of PGD on lung transplant outcomes has been historically unclear due to variability in the definition. A consensus statement in 2005 sought to standardize the definition and severity of PGD (Table 39-7).¹⁶⁴ Studies examining outcome utilizing the current grading system have demonstrated a direct correlation with severity of PGD and ICU mortality, in-hospital mortality, 1-year survival, and freedom from BOS.^{165,166}

Table 39-7 Grading of Primary Graft Dysfunction Severity

Grade	PaO ₂ /FIO ₂	Radiographic Infiltrate Consistent with Pulmonary Edema
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

Rejection

Acute rejection episodes often occur soon after transplantation, usually between posttransplantation days 5 and 7. Two or three rejection episodes can occur within the first month. Mild temperature elevation, perihilar fluffy infiltrates, or a minimal decrease in oxygenation as measured by arterial oxygen tension may indicate the onset of acute rejection. Because rejection occurs so frequently during this period, the distinction between infection and rejection may be difficult. Often, the distinguishing factor between these two entities is that rejection responds positively to the administration of corticosteroids. Treatment of early rejection involves the use of bolus corticosteroids given on 3 consecutive days. Within 12 to 18 hours after the first corticosteroid dose symptoms relating to rejection usually resolve including clearing of infiltrates on chest radiograph.

Transbronchial biopsies are performed to diagnose and monitor rejection, but the number of biopsies required to maximize specificity is large. One group recommends obtaining 18 separate transbronchial biopsy specimens to achieve 95% specificity. Transbronchial lung biopsy can also be used when the issue of rejection versus infection is not resolved after steroid administration. Flexible bronchoscopy can be performed at the bedside, and 6 to 10 separate biopsies can be obtained under fluoroscopic guidance. When symptoms or signs of rejection persist despite adequate treatment, open lung biopsy may be considered.

Infection

Infection in the posttransplantation period continues to be a significant cause of morbidity and mortality and is the most common overall cause of death. Posttransplant prophylaxis strategies targeting gram-positive and gram-negative bacteria, *Pneumocystis pneumoniae*, cytomegalovirus, and *Aspergillus* have been shown to decrease the morbidity and mortality from infectious complications. Bacterial pneumonia usually responds to appropriate antibiotic therapy, and patients are maintained on broad-spectrum antibiotics until specificities are determined by culture from the donor and recipient bronchus sent at the time of transplantation. Antibiotic administration is particularly important if one predominant organism is grown from the donor bronchus, and the recipient is maintained on an appropriate antibiotic or combination of antibiotics for at least 1 week. The most common organism recovered from donor bronchial washings is *Staphylococcus aureus*. In a series of 32 transplants, this organism was recovered from donors 11 times and subsequently from 4 transplant recipients.¹⁶⁷ Other commonly recovered pathogens include *Enterobacter* species and *Candida albicans*. The presence of organisms cultured from donor bronchial washings, however, does not absolutely predict the development of invasive infection in recipients. Less than half of recipients from whom organisms were recovered developed invasive infections.

The second most significant pathogen is cytomegalovirus (CMV). The diagnosis of CMV is usually made from culture of BAL fluid or tissue obtained from transbronchial lung biopsy. In the pulmonary transplantation population, CMV pneumonitis is the predominant form of CMV infection, although CMV enteritis and retinitis also occur. This observation corresponds to that seen in cardiac and cardiopulmonary transplant recipients. About half of lung recipients develop documented CMV infection. Ganciclovir has proved particularly effective and is the drug of choice for CMV infection in this circumstance. The drug is well tolerated in most patients, with neutropenia accounting for most of the toxicity. CMV prophylaxis with ganciclovir can be used for CMV-positive recipients or in those recipients who receive a lung from a CMV-positive donor. The mortality rate from life-threatening CMV infections treated with ganciclovir has been reported at 10%, far better than the 40% or greater mortality reported before this agent was available.¹⁶⁸ Life-threatening CMV infection can occur in CMV-negative recipients who receive a lung from a CMV-positive donor (primary infection) or in recipients who are already CMV positive (secondary infection). Cytolytic therapy especially with muromonab-CD3 is associated with an increased risk and severity of CMV infection. Mismatched donor–recipient CMV status also appears to be a significant univariate risk factor for mortality following retransplantation.¹⁶⁹ Attempts to match a CMV-negative recipient with a CMV-negative donor lung, given the shortage of donor organs, can prolong candidate waiting times. Based on the 2012 OPTN Annual Data Report, the

donor and recipient CMV status was either matched (positive-positive or negative-negative) or mismatched with a CMV-positive recipient and a CMV-negative donor in 70% of lung transplants performed from 2008–2012.²³

An analysis of UNOS outcomes data demonstrated that donor–recipient CMV serologic mismatch, particularly donor-positive/recipient-negative (D+/R–) serologic status, was a significant adverse risk factor for posttransplantation mortality in earlier eras (1990 to 1994 and 1995 to 1999) but not in a more recent era (2000 to 2004) of pulmonary transplantation, when compared with donor-negative/recipient-negative transplants.¹⁷⁰ These findings suggest that donor–recipient CMV mismatch can be an adverse factor for posttransplant survival but that this effect can be significantly decreased with the introduction of more effective CMV antiviral therapy.¹⁷¹

Infection with *Aspergillus* species is the most common fungal infection after lung transplant and occurs in 15% to 35% of recipients. Overall mortality is high (52%), especially with invasive infections (80%).¹⁷² Preemptive antifungal therapy has been shown to decrease the incidence of clinical fungal infection from 69% to 31%.¹⁷³

Airway Complications

Airway complications can significantly affect quality of life with repeated procedures, office visits, and hospitalizations. Airway complications can be categorized by the time course of occurrence (early vs. late) and the type of complication (stenosis, dehiscence, granulation, fistula, or infection). The incidence of airway complications has decreased substantially over time. This is likely due to improvements in lung preservation, surgical technique, and antibiotic prophylaxis. Airway complications are associated with persistent ischemia, infection, and rejection.

During the early pulmonary transplantation experience, problems with airway healing occurred in 60% to 80% of patients and resulted in death in 2% to 3%.¹⁷⁴ Patients often did well for the first 3 weeks after transplantation, and then the bronchial anastomosis dehisced, often with erosion into the pulmonary artery. Bronchial anastomotic healing was initially facilitated by withholding maintenance corticosteroids until after the first posttransplantation week and using an omental pedicle wrapped around the anastomosis. Historically, most problems with airway healing occurred after *en bloc* double lung transplants, which involves a tracheal anastomosis. Double lung transplantation required extensive dissection in the subcarinal space, resulting in the disruption of a number of bronchial collateral vessels. Since this operation was modified to one involving bilateral, sequential lung implantation with two bronchial anastomoses, airway problems are now infrequent, occurring in 10% to 15%, and rarely result in recipient deaths.^{175,176} The development of cyclosporine, advances in lung preservation, and better postoperative care have also improved airway healing. Immunosuppression, especially with high-dose steroids, may increase the risk of infection and decrease wound healing,^{177,178} and sirolimus should be avoided perioperatively for 90 days due to significantly increased rates of airway dehiscence.^{178–180}

The use of a telescoping bronchial anastomosis, in which the donor bronchus is intussuscepted into the recipient bronchus or vice versa, obviated the need for the omental pedicle wrap, allowed for immediate use of corticosteroids and reduced the anastomotic dehiscence rates. However, the telescoping anastomosis can increase the rate of anastomotic stenosis with complications in up to 48%¹⁸¹ and a stenosis rate of 7%.^{181,182} Recently there has been a trend toward the use of primary end-to-end anastomosis using figure-of-eight sutures with the anastomosis performed as close to the secondary carina as possible.^{149,183} Initial results demonstrate a lower incidence of stenosis with an equivalent rate of dehiscence of approximately 2%.^{149,150} Minimizing the length of the donor bronchus is important since perfusion of the anastomosis depends initially on retrograde collaterals from the pulmonary artery.^{184–186}

Risk factors for airway complications include the duration of donor mechanical ventilation, height mismatch, length of the donor bronchus, type of anastomosis, size mismatch, infections, airway ischemia, immunosuppression used, PGD, positive pressure ventilation, and acute rejection.^{178,179,181,185,187} Infections may increase inflammation and decrease healing, and resistant bacteria and fungal colonization are frequently present at the time of the anastomosis.

Management options depend on the type, location, timing, and severity of airway complication. Complications can occur at the anastomosis or more distally in 2.5% to 3% of patients with the extreme case being the vanishing bronchus syndrome with a mean survival of 25 months.^{188,189} Bronchial stenosis is the most common and occurs in 1.6% to 32% of transplants.^{181,189,190} Necrosis and dehiscence result in bronchial strictures. Some degree of dehiscence occurs in 1% to 10% of cases.¹⁹¹ Infections such as *Aspergillus* and early rejection have also been associated with stenosis.¹⁹² Patients may present

with cough, postobstructive pneumonia, dyspnea, atelectasis or lobar collapse on chest x-ray, and worsening FEV₁ on spirometry. Other types of airway complications include malacia, dehiscence, and fistula. A persistent air leak, pneumothorax, or pneumomediastinum may suggest airway dehiscence, and the most severe cases may require open repair, flap bronchoplasty, or even retransplant,¹⁹³ although a partial dehiscence may heal without further intervention.

Chest CT with 3D reconstructions can be helpful in planning interventions.^{194,195} Bronchoscopy plays a key role in diagnosing, and managing airway complications. Dilation can be performed using a balloon, rigid bronchoscope, or various dilators including Savary or olive tip dilators. Balloon dilation is the only procedure required in 26% of cases¹⁹⁶ and relieves symptoms in 94% of patients,¹⁹⁷ although most patients require repeat procedures. Rigid bronchoscopic dilation allows for direct visualization of the stricture and ventilation during dilation. Ablation can be performed with laser, argon plasma coagulation, or cryotherapy. For refractory lesions, submucosal injection of steroids or topical mitomycin-C may help prevent recurrence.^{198–200}

Stenting should be considered when other more conservative interventions have failed. Stents can provide symptomatic relief in 80% to 94% of patients with long-term patency in 45%.^{197,201} However, complication rates up to 54% have been reported^{202–204} and should be carefully considered when placing a foreign body in an immunocompromised patient. Bacterial colonization is seen in up to 78% of cases,^{201,205,206} and complications include infection, granulation tissue, and stent migration. Stents have also been associated with higher rates of respiratory infections in cancer patients.²⁰⁷ Metal stents can become embedded in granulation tissue making removal hazardous. Covered stents should be used when possible and should be removed once they are no longer needed. Stents can also be used to temporarily cover a dehiscence to allow healing over several weeks²⁰⁸ although care must be taken not to extend the injury during stent placement and removal.

Self-expanding stents are easy to place through a flexible scope; however, silicone stents offer certain advantages including decreased granulation tissue, the ability to customize and modify the stents, and the ease of removing the stents,²⁰⁹ although stent migration and mucous plugging are still possible. If endoscopic therapies are unsuccessful, sleeve resection, lobectomy, and pneumonectomy have been reported but carry significant risks of morbidity and mortality.

Bronchomalacia may occur with loss of cartilaginous support of the airway due to ischemia or infection. Patients have a “barking” cough, shortness of breath, wheezing, and recurrent infections. Bronchoscopy and dynamic CT with inspiration and expiration images are important for diagnosis. Patients are treated with mucolytics and noninvasive positive pressure ventilation. In severe cases, stents may be used and can increase spirometry results.¹⁹⁶

The lungs have a dual blood supply with perfusion from systemic bronchial arteries as well as the pulmonary arteries, although generally only the pulmonary arterial circulation is restored during transplantation. The anatomy of the bronchial arteries is variable with 1 to 4 arteries arising from the descending aorta and the upper right intercostal arteries.²¹⁰ Bronchial artery revascularization may improve airway healing and decrease airway complications.^{211–214} The largest series from Copenhagen showed an improved 5-year survival of 69% after bronchial artery revascularization versus 57% without.²¹⁵ There are also studies showing decreased incidence of pulmonary infections and a trend toward increased freedom from BOS at 24 months.²¹⁶ Bronchial artery revascularization is technically challenging, leading to longer ischemic times and increased risk of bleeding, and with the limited published data, has not been widely adopted.

Bronchiolitis Obliterans

7 Acute and chronic rejection continues to be higher after lung transplant than other solid organs. Bronchiolitis obliterans remains the leading cause of late mortality following lung transplantation with nearly 30% of deaths beyond the first year of transplantation attributed to the fibroproliferative changes and airway destruction of this disorder. BOS is present in the first year in 7.9% of patients and in 43% by 5 years,²³ and remains a significant cause of morbidity. Following heart–lung transplantation, nearly 50% of deaths beyond the first year are attributable to bronchiolitis obliterans and pulmonary graft failure.¹⁷

BOS is defined as a decline in FEV₁ of greater than 20% from baseline determined on at least two separate measurements obtained at least 3 weeks apart.²¹⁷ The histologic appearance of bronchiolitis obliterans is characterized by progressive small airway destruction, an inflammatory exudate, and fibrosis. This complication is likely a form of chronic rejection, although its exact etiology remains unknown. If diagnosed early, enhancing immunosuppression may either halt the process or slow its

progression. Factors associated with BOS include repeated episodes of acute rejection, chronic rejection, infection, and gastroesophageal reflux disease.^{218–220} It has been hypothesized that the development of obliterative bronchiolitis in cardiopulmonary transplantation patients is related to a human major histocompatibility complex (human leukocyte antigen)–A2 antigen mismatch. Others believe that CMV infection or early lung injury, such as that arising from PGD, may be implicated.²²¹ Once diagnosed, it is important to increase immunosuppression to prevent what is usually an insidiously progressive disorder. Unfortunately, in patients who have developed obliterative bronchiolitis and then undergo retransplantation, the pathology can recur in the newly transplanted lungs. Obliterative bronchiolitis remains the major problem in patients surviving for greater than 2 years following transplantation. Overall, long-term survival for lung transplantation is not likely to improve significantly until effective strategies for the prevention and treatment of obliterative bronchiolitis are identified.

New terminology has been recently introduced to include other chronic forms of decreased lung function after transplant.²²² Chronic allograft dysfunction, or CLAD, is defined as an irreversible decline in FEV1 to < 80% of baseline. In addition to BOS, restrictive allograft syndrome presents with restrictive findings on PFTs including a decline in total lung capacity to < 90% of baseline and has a worse survival than other patients with CLAD.²²³

GASTROESOPHAGEAL REFLUX

8 After lung transplantation, patients have a higher rate of gastroesophageal reflux disease,²²⁴ and the incidence is increased after bilateral transplant and retransplantation.^{225,226} Reflux is found in 90% of patients with CF^{7,227} and high rates of reflux and dysmotility are associated with connective tissue disorders.²²⁸ Compared to nontransplant patients, pepsin is increased in BAL fluid in patients after lung transplant.^{229,230} Increased reflux may be a result of immunosuppressive medications or changes from the surgical procedure itself, possibly due to the proximity of the vagus nerve.^{231–233} Reflux in lung transplant patients has been associated with aspiration, impaired lung function, and decreased survival. Bronchiolitis obliterans has been associated with gastroesophageal reflux.^{220,230,234–236} Cytokines and cellular activation are increased in BAL fluid secondary to chronic gastroesophageal reflux and may lead to the production of alloantigens and BOS.^{237,238} Decrease in mucociliary clearance in transplant patients may also make the effects of aspiration worse.^{232,239} Reflux may lead to chemical injury,²⁴⁰ and bile acids may inhibit immune mechanisms by lowering levels of surfactant involved in regulating cytokines and the immune response.²³⁴ Studies have found an association between reflux and episodes of acute rejection.^{230,235,237,241}

Lung transplant patients with abnormal pH probe testing have an increased rate of decline in their FEV1, and the decline is worse when patients do not undergo antireflux surgery.²²⁰ One study of 215 patients found that abnormal preoperative pH testing was associated with significantly decreased survival.²⁴² Nonacid reflux is also increased after lung transplant, and heartburn symptoms were poor at predicting the presence of pepsin or bile in BAL fluid.^{243,244} In addition, suppressing acid with H2 blockers or proton pump inhibitors did not stop the effects of aspiration or the development of bronchiolitis obliterans.²⁴⁵ Antacid therapy may result in silent aspiration and also contribute to bacterial overgrowth, which could increase injury from aspiration.²⁴⁶ Thirty-six percent of patients with reflux also had esophageal dysmotility.²²⁵ Gastroparesis is present in 50% of lung transplant patients before transplant, increasing to 74% postoperatively; a significant number of patients return to normal function with time.²⁴⁷

Antireflux surgery decreases both acid and nonacid reflux and can be safely performed in lung transplant patients^{228,233,248,249} either prior to or after their transplant depending on their functional status. Antireflux surgery decreases immune factors associated with BOS and preserves overall pulmonary function^{220,233,250,251}; data on any survival benefit is limited with only one study showing a survival benefit at 1 year after early fundoplication within 90 days.²⁵²

FUTURE CONSIDERATIONS

The number of lung transplants continues to increase with 1,922 lung transplants performed in 2013 and 2,474 patients added to the waiting list. Pulmonary transplantation has evolved from an experimental therapy to the standard of care for patients with certain end-stage pulmonary diseases. The number of transplanted patients older than 65 has increased substantially over the past 10 years, and patients are

sicker with a higher median LAS. Careful patient selection by a multidisciplinary team is essential. As waitlisted patients become sicker, with acute inpatient evaluations becoming more common, the use of ambulatory ECMO may increase to help prevent these patients from becoming deconditioned. Work also continues on developing long-term paracorporeal support devices including the artificial lung.

Donor availability remains a limiting factor and efforts to increase the number of acceptable donor lungs will continue including aggressive donor management, evaluation of marginal lungs using EVLP, and consideration of DCD lungs. Future developments in EVLP may also allow biomarker assessment to evaluate donor lung injury as well as therapeutic interventions during ex vivo perfusion.⁸⁷ Research is also being done to regenerate decellularized lung scaffolds using EVLP.^{253,254}

Chapter 40

Pancreas and Islet Transplantation

Randall S. Sung

Key Points

- 1 The Diabetes Control and Complications Trial (DCCT) demonstrated that tight control of blood glucose and minimization of hemoglobin A1C delays the progression of secondary complications of diabetes.
 - 2 Recipients with functioning pancreas transplants have normal glycemic control without the need for exogenous insulin, and pancreas transplantation has a beneficial impact on diabetic complications.
 - 3 Pancreas graft survival rates are 90% at 1 year.
 - 4 Most pancreas transplants are performed in patients with end-stage renal disease (ESRD), either concomitant with or following a kidney transplant.
 - 5 In general, eligibility criteria for pancreas transplantation are more stringent than for kidney transplantation alone.
 - 6 Pancreas transplant outcome is dependent on the careful selection of donors and on meticulous pancreas procurement technique.
 - 7 Immunosuppression for pancreas transplantation is similar to that for kidney transplantation.
 - 8 In contrast to kidney transplants, the effect of a pancreas transplant on patient survival is probably only modest.
 - 9 Islet transplantation does not require an operative procedure.
 - 10 Although early outcomes are excellent at major islet centers, long-term rates of insulin independence are worse than whole-pancreas transplants, but continue to improve.
-

Diabetes mellitus is a spectrum of impaired glucose tolerance that ranges from gestational glucose intolerance to severe hyperglycemia and ketoacidosis. Diabetes, which affects approximately 8% of the U.S. population, can be divided into two major classifications. Type 1, previously referred to as insulin-dependent diabetes, is an autoimmune disease characterized by the eventual loss of all pancreatic β -cell function. Type 2 diabetes, previously referred to as non-insulin-dependent diabetes or adult-onset diabetes, characteristically presents in obese patients over age 40.¹ Many of these individuals eventually require insulin therapy. The incidence of type 2 diabetes is increasing as the prevalence of obesity increases, especially in younger age groups. The annual percentage change for age-adjusted prevalence and incidence of diagnosed diabetes did not change significantly during the 1980s, but increased sharply each year during 1990 to 2008 before leveling off with no significant change during 2008–2012.² Analyses of nationally representative data from 1980 to 2012 suggest a doubling of the incidence and prevalence of diabetes during 1990–2008, and a plateauing between 2008 and 2012. There appear to be continued increases in the prevalence or incidence of diabetes among subgroups, including non-Hispanic black and Hispanic subpopulations and those with a high school education or less.

While the mean age of onset is in the early teenage years, the disease may present as early as the first year of life. Type 1 diabetes afflicts approximately one in every 400 to 500 children and adolescents.³ Patients may present as late as the fourth decade of life, and these patients may be misclassified as type 2 diabetics, despite clearly possessing the physiology of type 1 diabetes. The disease classically presents in a lean patient with polyuria, polydipsia, and polyphagia. It may present at the time of a concurrent illness. While there may be a brief “honeymoon” period after presentation where insulin is not required, exogenous insulin is always required to replace that lost by the complete destruction of β -cell mass. While hyperglycemic episodes from poorly controlled diabetes, or hypoglycemic events from insulin, may be life threatening, the major morbidity of type 1 diabetes stems from the myriad long-term manifestations of the disease, particularly those that are due to accelerated atherosclerosis.

PATHOPHYSIOLOGY

The classic pathophysiology of diabetes is that of insulin secretory failure in type 1 diabetes and peripheral insulin resistance in patients with type 2 diabetes. The etiology, epidemiology, and pathogenesis of diabetes are much more complex than is reflected in early characterizations of the disease. Type 1 diabetes is classically described as an autoimmune disorder manifest by destruction of β -cells, with proinsulin being the most likely primary target.⁴ Although there are rare monogenic, immune-mediated forms of type 1 diabetes, the common form is thought to be determined by multiple genetic and environmental factors. The concordance for type 1 diabetes in monozygotic twins is less than 100%, and although type 1 diabetes aggregates in some families, it does not segregate with any clear mode of inheritance.⁵

There is multigenic susceptibility to type 1 diabetes. Genes within the HLA region, especially those that encode antigen-presenting molecules, confer the greatest part of the genetic risk of type 1 diabetes. The likelihood that these many genes may individually only have weak effects make them more difficult to identify precisely, and may explain the heterogeneity of inheritance of type 1 diabetes. This genetic susceptibility background is thought to interact with environmental triggers, perhaps infectious, that lead to autoimmunity and insulinitis, the characteristic pathologic lesion of type 1 diabetes, although definitive proof of these triggers is lacking.

The incidence of type 1 diabetes has been progressively increasing during the past several decades, particularly among children younger than 5 years. In children at genetic risk, diabetes-related autoantibodies appear, followed by the evolution of metabolic abnormalities and the eventual clinical appearance of the disease. If individuals identified by genetic markers subsequently undergo seroconversion and develop two or more diabetes-related autoantibodies, their risk of progression to type 1 diabetes is 75% over 10 years and appears to be almost certain over 20 years.⁶ Attempts at primary prevention before seroconversion, and secondary prevention in those with diabetes-related autoantibodies, have not been successful.⁷ The interventions evaluated to date have been very low risk since they are designed to be used in at-risk individuals who may or may not progress to type 1 diabetes.

Mucosal tolerance has been exploited in secondary prevention studies using nasal insulin and in secondary prevention and recent-onset type 1 diabetes studies using oral insulin.⁸ However, these studies have not been successful in altering the course of the disease. In the Diabetes Prevention Trial–Type 1 (DPT-1), a secondary prevention study of oral insulin, those with high levels of insulin autoantibodies at baseline had a projected 4.5- to 5-year delay in the development of clinical diabetes. A subsequent analysis showed continued beneficial effects even after oral insulin was discontinued.

In type 2 diabetes, while β -cell hypersecretion initially may exist, ultimately loss of β -cell mass ensues. β -Cell apoptosis is mediated by glucotoxicity from insulin resistance, and is exacerbated by fatty acids, lipoproteins, leptins, and cytokines, all of which are elevated in type 2 diabetes and obesity.⁹ Because of peripheral insulin resistance, many patients require insulin in amounts that exceed one unit per kilogram, far greater than typically required by type 1 diabetics.

The observation that type 1 and type 2 diabetes frequently cooccur in the same family has raised the possibility that they are opposite ends of the same disease spectrum, and ample evidence suggests the two are more similar than initially believed.^{10,11} Families with mixed diabetes histories tend to have an intermediate diabetes phenotype: insulin resistance in type 1 and lower BMI and C-peptide concentrations in type 2 patients. β -Cell destruction is common to both types, and obesity and insulin resistance have both been shown to be risk factors for childhood type 1 as well as type 2 diabetes. The “accelerator hypothesis” of diabetes proposes three determinants of disease in all types of diabetes: the intrinsic rate of β -cell apoptosis, insulin resistance, and autoimmunity (which would apply only to a subset). Genetic studies suggest there may be a common predisposition. However, the cytokines, signal transduction pathways, and other soluble mediators of apoptosis are quite different between the insulinitis of type 1 diabetes and the lipotoxic or glucotoxic processes of type 2 diabetes, and thus at minimum represent distinct mechanisms of β -cell destruction.¹²

The relatively recent discovery of the replicative potential of a variety of adult tissue types, and their roles in the pathogenesis of disease, has relevance to the pathogenesis of diabetes. In such a model, diabetes occurs due to a failure of regeneration of β -cells, and individual variation in the ability to regenerate β -cells is an important determinant of diabetes development. This hypothesis is partially supported by the finding of associations of type 2 diabetes with genes having identified roles in cellular development. While it is broadly agreed that failure of β -cell replication is an important contributor to diabetes development, increased susceptibility of replicating β -cells to apoptosis in a proapoptotic

environment may also lead to loss of β -cell mass. There is also evidence that deficits of β -cell secretion are as important as those of replication. Furthermore, the range of β -cell mass in adult diabetic and nondiabetic humans is very wide, and exceeds the apparent capacity for expansion of β -cell mass in response to regenerative stimuli. Thus it appears more likely that insufficient growth of β -cell mass during development may be more likely to have a role in the predisposition to diabetes than specific deficits in regeneration.¹³

Alternatively, β -cell dedifferentiation, rather than death, may be the mechanism responsible for β -cell failure in type 2 diabetes.¹⁴ When normal β -cells are challenged by mild hyperglycemia or insulin resistance, they produce and secrete more insulin, thus maintaining euglycemia. Current thinking suggests that oxidative stress and/or endoplasmic-reticulum stress results in β -cell dysfunction, leading to increased secretion of incompletely processed proinsulin, which may trigger apoptosis. Stressed β -cells may undergo dedifferentiation, decreasing expression of β -cell-specific genes, including the enzyme that processes proinsulin; this may explain increased proinsulin secretion in type 2 diabetes. Dedifferentiation may also promote expression of embryonic progenitor-cell markers, and these cells may later secrete non- β -cell hormones such as somatostatin and glucagon.

SECONDARY COMPLICATIONS OF DIABETES

Diabetes mellitus is responsible for tens of thousands of deaths each year in the United States. The high incidence of cardiovascular complications in diabetics is primarily responsible for the twofold increase in the risk of death in diabetics compared with those without diabetes.² Clinical complications of diabetes include end-stage renal disease (ESRD), retinopathy, peripheral vascular disease, coronary artery disease, and neuropathy. Diabetic nephropathy is responsible for nearly half of all cases of ESRD; diabetes is also the leading cause of blindness and amputations in the United States.¹⁵ In 2012, 1 in 5 healthcare dollars was spent to support the care of patients with diabetes at a total estimated cost of \$245 billion.¹⁶

Improvements in diabetes care have reduced the long-term impact to some extent. Rates of all five major diabetes complications (acute myocardial infarction, hyperglycemic crisis, stroke, amputations, and ESRD) declined between 1990 and 2010, with the smallest decline in end-stage renal disease. However, when expressed as rates for the overall population, in which a change in prevalence also affects complication rates, there was a decline in rates of acute myocardial infarction and death from hyperglycemic crisis, but not in rates of amputation, stroke, or ESRD. Thus, while rates of diabetes-related complications have declined substantially in the past two decades, a large burden of disease persists because of the continued increase in the prevalence of diabetes.¹⁷

While diabetic complications have a multifactorial etiology, they are ultimately secondary to structural alterations in nerves, blood vessels, and connective tissue. Excess glucose is converted to sorbitol by aldose reductase, leading to the reduction of cellular content of myoinositol, abnormal phosphoinositide metabolism, and reduction in Na^+ - K^+ -ATPase activity. In experimental animals, aldose reductase inhibitors prevent diabetic neuropathy, cataracts and retinopathy.¹⁸ The accumulation of advanced glycosylation end products (AGEs), due to abnormal nonenzymatic glycosylation of proteins, and extensive crosslinking of these proteins, is likely to be pathogenic.¹⁹ Ligation of endothelial cell receptors by AGEs results in the release of proinflammatory cytokines and activation of the coagulation cascade. Microangiopathy is characterized by thickening of capillary basement membranes, which increases with the duration of disease, and altered capillary permeability.

1 The Diabetes Control and Complications Trial (DCCT) demonstrated that tight control of blood glucose prevents and delays the progression of secondary complications of diabetes.^{20,21} This study, in which patients with type 1 diabetes were randomized to conventional treatment with one or two doses of daily insulin versus intensive treatment with three or more injections per day, demonstrated a dramatic reduction in the risk of progression of retinopathy, microalbuminuria, albuminuria, peripheral neuropathy, and cardiovascular disease in the subjects randomized to intensive treatment. However, the major side effect of intensive treatment was a threefold increase in the risk of severe hypoglycemic episodes; approximately 10% of patients in the intensive insulin therapy cohort experienced five or more episodes of seizure or coma during the study period. Even in the absence of overt brain injury, multiple episodes of severe hypoglycemia have been associated with cerebral perfusion abnormalities and poor neuropsychiatric performance. In addition, there is a significant risk of accident during hypoglycemic episodes. Frequently, as hypoglycemia becomes more frequent and autonomic neuropathy

worsens, patients may develop a syndrome of unawareness to hypoglycemia where the typical symptoms of tremor and anxiety do not occur. Such patients with hypoglycemic unawareness may develop profound hypoglycemia, especially if left unsupervised, and risk severe neurologic and traumatic injury.

In a similar trial, patients randomized to intensive insulin therapy, compared to those randomized to conventional therapy, had lower all-cause mortality. The most common causes of death were cardiovascular disease (22%), cancer (20%), and acute complications (18%).²² The long-term risk of an impaired glomerular filtration rate (GFR) was significantly lower among persons treated early in the course of type 1 diabetes with intensive diabetes therapy than among those treated with conventional diabetes therapy.²³ Notably, all-cause mortality was significantly higher among those with higher mean hemoglobin A1C (HbA1C) levels and with renal disease during the 20-year follow-up.²²

The overall management of diabetes is focused upon maintaining blood glucose as close to normal range as possible while attempting to minimize significant hypoglycemic episodes. Although the frequency and extent of hyperglycemia is important in the assessment of glucose management, long-term glycemic control is best assessed by evaluation of blood levels of hemoglobin A1C which measures the extent of glycosylation of hemoglobin. Although the incidence of diabetes is increasing, the overall treatment efficacy has improved. The use of subcutaneous insulin pumps is being increasingly employed, inhaled insulin has been used in selected patients, and infusion devices which also assess serum glucose and automatically adjust insulin dose accordingly are being developed.^{24,25} Fully automated artificial-pancreas systems have been developed which link glucose sensors with insulin pumps through computerized control algorithms, which dictate insulin delivery in response to real-time sensor data.²⁶ Recent studies that have been carried out in hospitals have shown that such systems can improve glucose control and reduce the risk of nocturnal hypoglycemia in children, adolescents, and adults. Although such studies are encouraging, the major challenge ahead is successful implementation of such systems outside the hospital.

In practice it is the rare diabetic who can maintain tight glucose control without hypoglycemic complications. In fact, in a study of type 2 diabetics designed to reduce cardiovascular complications through normalization of glycemic control, intensive therapy was associated with increased early mortality and no reduction of cardiovascular events.²⁷ Most type 1 diabetics, even if on optimal insulin therapy, are unable to maintain hemoglobin A1C levels in the normal range, and most will ultimately develop progressive diabetic complications.

PANCREAS TRANSPLANTATION

Overview

2 Pancreas transplantation, while not technically a cure, represents an important therapeutic insulin replacement option for many type 1 diabetics. Recipients with functioning pancreas transplants have normal glycemic control without the need for exogenous insulin. Initial experience with pancreas transplantation, from the first pancreas transplant performed by Kelly and Lillehei in 1966 until the 1980s, was marked by low success rates and high mortality.²⁸ In 1980 the 1-year graft survival rate for pancreas transplantation was only 21%, and there was tremendous skepticism about the utility of the procedure.

3 Advances in surgical technique and immunosuppression have dramatically improved current graft survival rates to around 90% at 1 year. In addition to the development of cyclosporine, the introduction of bladder drainage of the donor pancreas, first introduced by Sollinger in 1985 using a button of donor duodenum, and subsequently modified by Corry in 1986 using an entire segment of duodenum anastomosed to the urinary bladder, dramatically improved the results of pancreas transplantation (Fig. 40-1).^{29,30} Graft survival continued to improve throughout the 1980s and 1990s, especially for isolated pancreas transplantation (pancreas transplant alone [PTA], or pancreas after kidney transplantation [PAK]), the results of which have been historically inferior to simultaneous kidney-pancreas transplants (SPK). Both short- and long-term survival of pancreas transplants have slowly improved over the past decade. Because bladder drainage is associated with significant morbidity, most pancreas transplants are currently performed with enteric exocrine drainage and venous drainage into the systemic circulation. However, pancreas transplantation may also be performed by draining pancreatic venous blood into the recipient portal circulation, usually via the superior mesenteric vein.

Figure 40-1. Simultaneous pancreas kidney transplantation performed with drainage of the pancreatic exocrine secretions into the urinary bladder (bladder drainage). This technique has been predominant until recently. Note that a segment of the second portion of the duodenum is left attached to the pancreas. Despite its heterotopic location, the transplanted pancreas responds to gastrointestinal hormones with a marked increase in secretion of pancreatic juice that has very high bicarbonate content. Also note that the portal vein drains into the iliac vein (i.e., systemic venous drainage). In healthy individuals 50% of the secreted insulin is extracted from the circulation in the first pass through the liver. Transplant recipients with systemic venous drainage have peripheral insulin levels two to two and one half times higher than normal.

Patient Selection

Pancreas transplantation is usually performed in patients with type 1 diabetes. The diagnosis of type 1 diabetes is relatively straightforward for most individuals. A history of juvenile or young adult onset, diabetic ketoacidosis, a lean body habitus, and a low insulin requirement (<0.7 units/kg) all support the diagnosis of type 1 diabetes. In contrast, older age of onset, obesity, an interval of treatment with diet or oral agents, or high insulin requirements are all suggestive of type 2 diabetes. A subset of adult-onset diabetics will display characteristics otherwise associated with type 1 diabetes, including absence of insulin production. Whether these individuals are properly classified as type 1 or type 2 diabetics may be subject to debate, but these individuals may certainly benefit from pancreas transplantation. Individuals with type 1 physiology but adult age of onset and low but detectable C-peptide secretion may also be considered for pancreas transplantation. Approximately 5% of pancreas transplant recipients are classified as having type 2 diabetes, and outcomes for these recipients are similar to those with type 1 diabetes.³¹ As these are typically highly selected individuals without significant insulin resistance, most type 2 diabetics would not be considered candidates. Some type 1 diabetics may develop insulin resistance as a result of years of insulin therapy; this is frequently accompanied by increased body weight and insulin requirements. While insulin resistance may improve after transplantation in such patients, or may be managed with additional oral hypoglycemic agents, these patients are at higher risk for remaining on insulin after pancreas transplantation.³² While provocative tests for insulin resistance exist, they are not commonly employed.

A small percentage of pancreas transplant recipients do not have type 1 diabetes, but have diabetes from other causes. Several have undergone pancreatectomy for chronic pancreatitis or other conditions.³³ Some pancreas transplants ($<1\%$) are performed as part of a multivisceral transplant that includes liver and small intestine in patients who do not have diabetes; in these transplants, the pancreas is included in the graft to facilitate the technical conduct of the operation and to reduce complications.³⁴

4 Most individuals evaluated for pancreas transplantation have chronic renal disease. These patients may present prior to onset of dialysis, while currently receiving dialysis, or following kidney transplantation. For individuals without a functioning kidney transplant, potential options include simultaneous deceased donor kidney/pancreas transplantation (SPK), living donor kidney transplantation followed by PAK, simultaneous living donor kidney–deceased donor pancreas transplantation (SPLK), or simultaneous living donor kidney–pancreas transplantation. Of these options

the former two are by far the most common.

Simultaneous Kidney–Pancreas Transplantation

SPK from a deceased donor is the most commonly performed pancreas transplant option, with the number exceeding all other types combined. An SPK transplant has the advantage of requiring only one operation for both transplants. Since alloreactivity against the transplanted pancreas tends to be concordant with activity against the kidney, pancreas rejection may be heralded by signs of kidney rejection, which are more sensitive and present earlier. Consequently, SPK pancreas outcomes have been historically superior to those of solitary pancreas transplants.

Pancreas After Kidney Transplantation

If a living kidney donor is available, candidates have the option of receiving a living donor transplant, followed by a deceased donor pancreas transplant. This approach has the disadvantage of requiring two separate operations, but the recipient enjoys the benefit of a living donor kidney transplant that in many circumstances occurs sooner than would an SPK from a deceased donor. Since the primary survival benefit of the kidney–pancreas transplant comes from the restoration of renal function, this is a significant advantage. However, since a PAK is essentially a solitary pancreas transplant immunologically distinct from the kidney transplant, pancreas outcomes are worse than for SPK.

Simultaneous Living Donor Kidney–Deceased Donor Pancreas Transplantation

SPLK is another option performed at a few centers.³⁵ Candidates with identified living donors are listed for deceased donor pancreas transplantation. When a deceased donor pancreas becomes available, the living kidney donor transplant is performed at the same time as the pancreas transplant. This approach has the advantages of sequential living donor kidney followed by PAK transplants while requiring only one operation. It does require that the potential living donor be available to donate at any time, a requirement that excludes some donors from this approach. It also has the disadvantage of potentially delaying a kidney transplant for the recipient if the waiting time for a deceased donor pancreas is long. However, since waiting times for solitary pancreas in some areas of the country can be quite short, the advantages may be substantial.

Living Donor Kidney–Pancreas Transplantation

A few centers perform living donor kidney–pancreas transplantation, with a single living donor donating the tail of the pancreas as well as the kidney (Fig. 40-2). This approach has all the advantages of a single operation, a single donor, and no waiting time. Results have been comparable to deceased donor SPK transplants.^{36,37} Widespread adoption of this approach has been limited by concerns about donor morbidity from the pancreatectomy. Serious complications such as pancreatitis, fistula, abscess, or pseudocyst can occur. Glucose intolerance and frank diabetes have occurred, although this problem has been nearly eliminated with more stringent donor selection criteria.^{37,38}

Pancreas transplant candidates with renal failure may be counseled in a variety of ways depending on the availability of a living donor. How individuals are counseled depends in part on factors particular to the potential living donor and recipient, and also on the expected waiting time for SPK and PAK transplantation, which vary greatly by geographic region. Since the mortality benefit of a kidney–pancreas transplant derives primarily from the kidney transplant, priority is generally given to achieving kidney transplantation expeditiously. In geographic regions where the waiting time for SPK is long (5 years is not unusual), living donor kidney transplantation is advised. Recipients of living donor kidney transplant can then be listed for PAK which can be performed following recovery from the living donor kidney transplant. Individuals without living donors or those with borderline living donors in areas with short waiting times can be listed for SPK. Interestingly, there does not appear to be the same adverse impact in outcome with a limited interval of pretransplant dialysis (less than 2 years) in SPK recipients that is observed in kidney-alone recipients, whether deceased or living donor.³⁹ Therefore, even candidates with living donors may reasonably opt for SPK if anticipated waiting times are short.

Pancreas-Alone Transplantation

A small number of type 1 diabetics are evaluated for PTA. These individuals are generally extremely labile diabetics who have progressive complications but do not have nephropathy. In these individuals the risk–benefit equation is quite different than those uremic diabetics evaluated for kidney–pancreas

transplantation. For nonuremic diabetics evaluated for pancreas transplantation the risk of immunosuppression in addition to the surgical procedure must be weighed against the potential benefits from transplantation. This contrasts to uremic diabetics, where the risk of immunosuppression is already assumed by virtue of the need for a kidney transplant. This risk includes renal failure due to chronic calcineurin inhibitor use. This is commonly cited as justification to not perform PTA, and recent evidence suggests the 10-year risk is at least 20% and is related to pretransplant GFR.⁴⁰ Whether PTA for type 1 diabetes results in a significant survival benefit is controversial. PTA in most centers is generally offered only in the most exceptional cases, the most common indication being frequent life-threatening hypoglycemic events. However, several transplant programs exist that have a different philosophical outlook on the risks and benefits of PTA, and these referral centers generally perform large numbers of PTA. Most PTAs are from deceased donors, with a small number of centers offering living donor PTA. Living donor pancreas transplants carry a higher rate of technical failure but a lower rate of immunologic failure.^{41,42}

Figure 40-2. Live donor pancreas and kidney transplantation. **A:** Provided that the donor has a normal glucose tolerance test, a living donor may donate the segment of the pancreas that is to the left of the superior mesenteric vessels. **B:** Transplantation of tail of the pancreas is based on the splenic artery and vein.

Evaluation and Screening

5 In general, eligibility criteria for pancreas transplantation are more stringent than for kidney transplantation alone, since the operation and recovery are more rigorous, the potential complications more serious, and the benefits less pronounced compared with kidney transplantation. Candidates

should have excellent functional status in anticipation of the more extensive surgery and more frequent complications. Age is not tightly related to outcome, but patients over the age of 60 are carefully scrutinized.⁴³ A detailed history of the patient's diabetes and treatment is obtained, including current glycemic control, hypoglycemic events, secondary complications, insulin requirements, and overall quality of life. Obesity in and of itself is not a contraindication, as outcomes for carefully selected obese (BMI >30) recipients are similar to nonobese recipients, although surgical complications and the likelihood of remaining insulin dependent may be slightly higher.⁴⁴ Selection practices vary widely—for some centers, pancreas transplantation is reserved for those with significant complications and poor glycemic control who have failed alternative treatments, while for others the presence of type 1 diabetes and a full understanding of the risks and benefits are sufficient, with patient preferences playing a significant role. In general, because of the added need for immunosuppression in PTA, these diabetes-related criteria are much more stringent than for SPK or PTA, where the risk of immunosuppression is already assumed by virtue of the kidney transplant.

All candidates, in addition to assessment of the potential benefit of pancreas transplantation, should have at the least noninvasive cardiac stress testing such as dobutamine stress echocardiography or adenosine thallium stress scintigraphy. Potential candidates with reversible myocardial defects undergo coronary angiography, and many centers perform angiography on all candidates. The decision to perform pretransplantation coronary revascularization must be made with consideration of both peritransplant mortality and long-term survival. Although survival outcomes are diminished in recipients with coronary artery disease,⁴⁵ a history of coronary revascularization is not necessarily a contraindication; individuals with extensive myocardium at risk and without revascularization options are frequently excluded.

Screening for peripheral vascular occlusive disease is often performed. Although distal peripheral vascular occlusive disease is characteristic of longstanding diabetes, aortoiliac disease and femoral popliteal vascular disease may also be present. Femoral popliteal disease is generally not a contraindication to transplantation, unless there are clinical signs of arterial insufficiency such as severe claudication or nonhealing ulcers. The presence of iliac disease is more problematic, as it can compromise inflow to the transplanted organs or increase the risk for postoperative arterial complications. In addition, diabetics may have significant vascular calcification which could preclude transplantation even in the absence of flow abnormalities. Screening for peripheral vascular occlusive disease, in addition to a thorough physical examination, may include noninvasive flow studies and/or CT scanning to evaluate vascular calcification. Candidates with a history or examination findings suggestive of cerebrovascular disease should be screened for hemodynamically significant carotid occlusive disease.

Other evaluations, as with other types of organ transplants, are tailored to the individual medical history, and differ among centers. Screening for malignancy commonly includes mammography and pap smears for women, prostate-specific antigen levels in men, and colonoscopy. Individuals with a prior history of treated cancer and who are judged to be at low risk for recurrence are usually candidates following an appropriate disease-free interval. This interval is decreasing as greater experience with transplantation in individuals with a history of cancer has accumulated, and can be as little as 2 years for many solid epithelial tumors to none for carcinoma in situ or early prostate cancer.⁴⁶ Screening for chronic viral infections such as hepatitis B, hepatitis C, and HIV is commonly performed, and pancreas transplants in selected individuals with chronic hepatitis are being performed with increasing frequency.^{47,48} As with liver and kidney transplantation, early experience with pancreas transplantation in carefully selected individuals with HIV infection has been encouraging.⁴⁹ Social work and/or psychiatric evaluation is performed to rule out psychiatric disease, inadequate social environments, and other issues that may impact the recipient's ability to participate in posttransplantation management.

Figure 40-3. Number of U.S. simultaneous pancreas–kidney (SPK), pancreas after kidney transplantation (PAK), and pancreas transplantation alone (PTA) pancreas transplants performed by year. (Data from Scientific Registry of Transplant Recipients. 2013 Annual Report. Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2015).

The Kidney–Pancreas Waiting List and Recipients

The number of patients on the waiting list for a simultaneous kidney–pancreas transplant has decreased from a peak of 2,396 in 2005 to 2,076 in 2012.⁵⁰ The majority of patients are white (60%), though the percentages of white candidates is decreasing, while the percentage of African-American (24%) and Hispanic/Latino patients (13%) continues to increase. The number of patients on the waiting list has decreased since 2000 for all adult age groups except those in 50 to 64, and the age distribution has shifted upward. While the majority are ages 35 to 49 (57% in 2012), the percentage who are ages 50 to 64 is increasing (23% in 2012) and the percentage who are ages 18 to 34 (19% in 2012) is decreasing. The annual death rate on the SPK waiting list was 69 per 1,000 patient years in 2012, compared with 96 in 2006.

The number of SPK transplants performed has declined from 924 in 2006 to 801 in 2012 (Fig. 40-3). Median times to SPK have increased from 14.8 months for those registered in 2006–2007 to 16.2 months for those registered in 2010–2011. Time to transplant is longer for African-American and Hispanic/Latino recipients. While the majority of SPK recipients are white (65%) and males (64%), the percentage of SPK recipients who are African American (20% in 2012) and Hispanic (12% in 2010) is increasing. The age distribution of recipients parallels that of the waiting list.

The Pancreas Transplant Waiting List and Recipients

The number of patients awaiting isolated pancreas transplants in 2012 is also decreasing, with 413 patients awaiting PTA versus 528 in 2006 and 583 awaiting PAK versus 986 in 2006.⁵⁰ The increase in the number of patients waiting for isolated pancreas transplant in the last 5 years is largely due to a sharp decrease in the numbers of new registrations rather than an increase in transplants performed.

The great majority of patients awaiting isolated pancreas transplants are white (80% for PTA, 75% for PAK); there have been significant increases in the percentage of African Americans on the PAK and PTA lists over the last several years. Although women continue to constitute 54% of the PTA waiting list in 2012, they are only 46% of the PAK waiting list. The majority of patients awaiting both PTA and PAK are between 35 and 49 years old, but as with SPK candidates, the percentage of older patients listed for PAK and PTA has increased, with 36% and 30%, respectively, of the waiting list in 2012 being between the age of 50 and 64 years.

The median time to transplant for PAK has increased over the last 5 years, with the mean waiting time for candidates registered in 2008–2009 now being 36.9 months. This is greater than the median time to transplant for SPK registrants. Wait times for PTAs have also increased, nearly doubling since 2007–2011 to 19.1 months for those registered in 2010–2011.

The age and race of recipients of solitary pancreas transplants reflect the waiting list. In 2012, 88% of PTA and 72% of PAK and recipients were white. More PAK recipients (64%) were male, but more PTA recipients (63%) were women, and this gender gap has widened in the past 5 years.

Deceased Donor Pancreas Allocation

As with many organs, deceased donor pancreas allocation is determined primarily by geography, with most organs offered to centers in the Donation Service Area (DSA) of donor origin. The base organ

allocation unit is the organ procurement organization (OPO) which serves the population within the DSA. The 58 DSAs are organized into 11 regions, which serve as the second-tier of organ allocation. As with other organs, pancreata are allocated according to nationally determined policies.⁵¹ There is mandatory sharing of pancreata to highly sensitized candidates that are completely matched to the donor; beyond this, pancreata are allocated to these pancreas candidates first locally, then regionally, then nationally based primarily on waiting time.

If the pancreas candidate is an SPK candidate, then a kidney from the same donor is usually also allocated to the SPK candidate, regardless of the candidate's place on the kidney waiting list. While such a policy promotes pancreas utilization, it has been somewhat controversial, since preferential allocation of kidneys to simultaneous kidney-pancreas (SPK) candidates prevents allocation to kidney-alone candidates who have generally been waiting longer. Solitary pancreata are more difficult to place compared with SPK because their outcomes are slightly worse, but are more easily shared voluntarily since OPOs have no obligation to share kidneys along with pancreas for outside SPK candidates; since pancreas donors are carefully selected, the kidneys from these donors are usually able to be transplanted into a local kidney candidate. Thus, shared pancreata are generally restricted to PTA or PAK candidates.⁵²

Pancreas allocation is also complicated by the fact that the pancreas donor selection criteria for islet transplant and whole-organ transplant overlap, leading to competition among certain types of organs. In determining whether a given pancreas will be allocated to a solid organ or islet transplant candidate, donor age and BMI are considered. Donors under age 50 and with BMI <30 are allocated for whole-organ pancreas transplant locally. If there is no local acceptance, the pancreas is offered regionally and then nationally. If there is no candidate for whole pancreas, the pancreas is then allocated for islets. For donors older than age 50 or with BMI >30, whose pancreata are rarely used for whole-organ transplant, the organ is first offered for pancreas transplant locally; if there are no local candidates, the pancreas is then offered for islets.⁵¹

Pancreata are significantly underutilized compared to other solid organs such as liver and kidney. As discussed below, donor selection criteria are more rigorous. Restrictions on cold ischemia time for whole-pancreas transplantation and particularly for islet transplantation make the placement of pancreata that are not used by the recovering center difficult. There is significant geographic variation in pancreas use, which correlates with activity by local transplant centers.⁵³

Donor Evaluation

6 The selection of appropriate pancreas donors is perhaps the most important determinant of successful pancreas transplantation. Many of the early complications of pancreas transplantation are thought to be secondary to processes related to organ quality and preservation, rather than the technical conduct of the recipient operation. While the ideal donor is young, nonalcoholic and nonobese, very few donors meet this description, and the surgeon frequently needs to consider pancreata from imperfect donors. Donor selection criteria may vary among surgeons and transplant centers, and may depend upon past experience, waiting time, and recent outcomes. Primary criteria are the age of the donor, donor BMI, donor cause of death, and the gross appearance of the organ at the time of recovery. Additional information that may influence the decision include aspects of the medical and social history, donor hemodynamics, laboratory values, HLA matching, and anticipated preservation time. As with donor selection with other organs, the decision-making process often involves consideration of multiple factors in aggregate.

The importance of donor age on graft outcomes has been confirmed by multiple studies, and the maximum age threshold is significantly lower than for liver and kidney transplantation.^{54,55} Many centers use an age threshold, which may range from 40 to 50, above which donors are selected very carefully. The mechanism by which age affects outcomes is not firmly established: age appears to influence both early technical and late graft loss.^{55,56}

Donor BMI has been found to be a determinant of graft failure by single-center and transplant registry analyses.^{57,58} Very few pancreata from donors with BMI greater than 30 are used for solid-organ transplant, and are more likely to be recovered for islet transplant.⁵² Interestingly, for overweight but not obese donors (BMI 25 to 30), a large single-center study found a higher rate of technical failure for donors who also had a cerebrovascular attack as cause of death.⁵⁷ It is not known whether associations with BMI relate to fatty infiltration of the pancreas or by a separate mechanism.

The circumstances of death and the condition of the donor influence donor selection. Pancreata from donors with stroke as a cause of death have reduced graft survival. Although experience from donors

after cardiac death (DCD) remains relatively limited (only 1.5% of all pancreas transplants in 2011), outcomes have been good with careful donor selection.^{50,59,60} Laboratory values, including serum amylase and lipase, play a relatively minor role in donor selection. Insulin administration is generally not considered a contraindication to pancreas donation. While the presence of donor hyperglycemia may raise concerns about latent diabetes, in most donors this reflects the rapid administration of dextrose-containing solutions, corticosteroids for cerebral edema, and high-dose catecholamines for blood pressure support rather than latent pancreatic endocrine insufficiency. Abnormal HbA1C has been utilized as a relative contraindication, but is not well studied and is not uniformly available for use. Evidence of injury to other organs such as liver and kidneys, as a marker of abdominal ischemia, while not ordinarily a contraindication, may be considered in marginal cases.

Donors with a history of type 2 diabetes, excessive alcohol use or pancreatitis may be used. A history of cardiovascular disease or cardiac risk factors are also not contraindications but may influence decision making or be associated with mesenteric atherosclerotic disease. A social history which suggests an increased risk of transmission of hepatitis or HIV should be evaluated, as with other organs, in the context of the degree of perceived risk relative to the benefit of the transplant.

Intraoperative evaluation of the donor organ is said to be the most important determinant of donor selection. Evidence of inflammation or fibrosis, which may manifest as focal or diffuse firmness to palpation, is considered to be a contraindication. Fatty infiltration of the pancreas, trauma and pancreatic edema are also adverse findings, although the latter may be correctable with donor management. Traumatic injury to the pancreas or hematoma within the substance of the pancreas would preclude transplantation. However, a prior splenectomy is not a contraindication, provided that the tail can be dissected atraumatically.

Factors not intrinsic to the donor may bear on the decision to perform a transplant. The higher risk of graft failure associated with solitary pancreas transplants leads some centers to have more stringent selection criteria for PTA and PAK. While cold ischemia is a risk factor for graft survival, pancreata from selected donors can be transplanted with cold ischemic times approaching 24 hours with good outcomes. Attention to HLA matching varies widely by center; the many analyses performed suggest that any relationships between matching and graft outcome that may exist are not likely to be very significant.^{56,58,61}

As for deceased donor livers and kidneys, a Donor Risk Index for pancreas has been described.⁵³ The pancreas DRI (PDRI) is based on 10 factors demonstrated to have significant impact on pancreas transplant outcomes. These include age, gender, race (black or Asian), BMI, height, CVA as cause of death, cold ischemia time, DCD, and terminal creatinine greater than 2.5 (Table 40-1). There is great variation in outcome by PDRI: the difference in graft survival at 1 year between the lowest 20% of PDRI (best outcomes) and the highest 20% is about 11% for SPK transplants and 16% to 17% for solitary transplants (Table 40-2). In addition to predicting outcomes for individual patients, indices like the PDRI are useful in assessing trends in pancreas utilization, which is quite variable by geography and by transplant center.⁵³

Procurement Technique

The importance of the pancreatic procurement cannot be overstated. It is thought by many pancreas transplant surgeons to be more critical to the success of the transplant than the recipient procedure. Because the pancreas is susceptible to traumatic injury, it must be carefully dissected and manipulated to avoid injury to the pancreatic parenchyma. Typically the pancreas is procured along with the liver and kidneys. This is performed in standard fashion through a midline incision which extends from the sternal notch to the pubic symphysis. After a generous Kocher maneuver, mobilization of the right colon, and isolation of the distal and supraceliac aorta to prepare these vessels for clamping, the pancreas is mobilized. This is most commonly achieved by entering the lesser sac, dividing the gastocolic omentum. This dissection continues with division of the short gastric vessels and the avascular gastrosplenic ligament. The pancreas is dissected from the pancreatic bed using the spleen as a handle. The tail is lifted from the pancreatic bed using blunt dissection and the occasional use of electrocautery. The proximal jejunum is dissected at the ligament of Treitz. An antibiotic and/or betadine containing solution are frequently instilled into the duodenum through a nasogastric tube for decontamination. The duodenum is divided both at the ligament of Treitz and at the pylorus using a stapler. Division of the middle colic vessels permits exposure of the proximal small bowel mesentery, which is divided distal to the pancreas with a vascular stapler. The mobilization of the pancreas may be performed either prior to or following the aortic perfusion procedure described below.

Perfusion of the pancreas is generally achieved through an intra-arterial cannula placed in the distal aorta following clamping of the supraceliac aorta and the aortic bifurcation. This is typically achieved with approximately 3 L of University of Wisconsin or HTK (histidine–tryptophan–ketoglutarate) solution while the entire abdominal organs are packed in saline slush. Preservation solutions are generally regarded to be equivalent, although a few studies suggest slightly worse outcomes with HTK.^{58,62,63} Some centers will also perfuse the abdominal viscera with a portal perfusion cannula, typically through the inferior mesenteric vein, although some surgeons maintain that overperfusion of either the arterial or the venous circulation may result in pancreatic edema and an increased risk of complications.

Table 40-1 Summary of Pancreas DRI

Donor Characteristics	Reference Donor (DRI = 1.00)	Change Factor Value to	DRI
Gender	Male	Female	0.87
Age	28	45	1.56
Black race	No	Yes	1.27
Asian race	No	Yes	1.17
BMI	24	30	1.17
Height (cm)	173	190	0.9
Cause of death: CVA/stroke	No	Yes	1.23
Cause of death: CVA/stroke in PAK	No	Yes	0.93
Pancreas preservation time (hrs)	12	20	1.13
DCD	No	Yes	1.39
SCr >2.5	No	Yes	1.22

The pancreas can be removed either en bloc with the liver and kidneys, en bloc with the liver, or separately, following removal of the liver. Whatever the technique, the portal triad is dissected out in cooperation with the liver procurement team. Typically the portal vein is shared by dividing it at the level of the coronary vein. Only in the rarest of circumstances should there be any difficulty using both the liver and the pancreas from the same donor even in the presence of hepatic arterial anomalies. In the presence of a replaced right hepatic artery, the superior mesenteric artery (SMA) can be divided just distal to the replaced right hepatic artery, leaving a very short cuff of SMA on the pancreas. Alternatively, the replaced right hepatic artery, if large enough to be safely reconstructed by the liver transplant team without a cuff of SMA, can be transected as it exists superiorly from behind the head of the pancreas. This is also true in the rare case where a completely replaced hepatic artery emerges from the superior aspect of the head of the pancreas; usually the artery in this case is long enough and large enough to be used for liver transplant without a celiac axis or aortic cuff. The bile duct and gastroduodenal artery are ligated on the pancreas side and divided on the liver side. Dissection then proceeds along the superior aspect of the pancreas along the proper hepatic artery. The splenic artery, which constitutes the other arterial blood supply to the pancreas, is divided a few millimeters from its origin to allow for adequate length on the pancreas while allowing the stump to be oversewn without compromising flow to the liver. Once the pancreas is removed or split from the liver, the pancreas is packed in preservation solution; the entire common iliac artery and its two main branches, the internal and external iliac arteries, are packaged along with the pancreas for back-table reconstruction. A graft

of donor iliac vein is also included in case the portal vein needs to be extended, which is done by some surgeons. Although most centers transplant the pancreas as soon as possible, up to 24 hours of cold ischemia time (time between perfusate infusion and organ reperfusion) has not been associated with reduced graft survival in carefully selected donors.^{53,56}

Back-Table Preparation of the Pancreas

The pancreas is placed on ice and remains cold at all times on the back table. The spleen is removed by dividing all vessels near the spleen, either by ligature or stapling, taking care to avoid injury to the tail of the pancreas which should be clearly identified. Some surgeons elect to wait until reperfusion of the pancreas in the recipient to remove the spleen. Significant peripancreatic fat, if left on at the time of procurement, should be trimmed. Both ends of the distal duodenum are shortened to the point where they are immediately adjacent to the head of the pancreas. Both stapled ends of the duodenum may be oversewn with silk or polypropylene sutures. Some surgeons elect to reinforce the mesenteric staple line by oversewing with polypropylene suture. The iliac artery Y-graft is typically attached by anastomosis of the internal iliac artery to the splenic artery and anastomosis of the externally iliac artery to the SMA (Fig. 40-4). In the absence of a Y-graft, the splenic artery may be implanted in end-to-side fashion to the SMA. The portal vein is mobilized by freeing from surrounding adventitial tissue to the confluence of the splenic vein and superior mesenteric vein. This should allow an adequate length of portal vein for anastomosis, as only 1 to 2 cm of portal vein length is generally needed.

Figure 40-4. Simultaneous pancreas–kidney transplantation performed with drainage of the pancreatic exocrine secretions into the proximal jejunum (enteric drainage). This technique has been adopted by most transplant centers in the United States for simultaneous pancreas–kidney transplants. For solitary pancreas transplantation, some centers still utilize bladder drainage to allow monitoring of the urinary amylase. Note that the donor portal vein drains into the recipient superior mesenteric vein (portal venous drainage), preventing peripheral hyperinsulinemia. Many centers continue to place the pancreas in the pelvis, combining enteric drainage and systemic venous drainage. This placement requires enteric anastomosis to a more distal segment of jejunum or ileum.

Recipient Operation

The pancreas transplant is typically performed through a midline incision, although a lower quadrant incision similar to a kidney transplant incision may be used. The recipient should receive broad spectrum antibiotics preoperatively. The pancreas transplant, for systemic venous drainage, is placed in the iliac fossa, preferably on the right side. After dissection of the recipient artery and vein, the portal vein is anastomosed in end-to-side fashion to the systemic vein. The distal inferior vena cava, common iliac vein, or external iliac vein may be used; the recipient vein segment should be mobile enough for

the portal vein to reach without tension. The common iliac artery component of the donor Y-graft is then anastomosed in end-to-side fashion to either the recipient external iliac artery or common iliac artery; the distal aorta can also serve as the site of anastomosis. A pancreas placed on the left side in the recipient may be placed either medial or lateral to the sigmoid colon. Multiple variations have been described.

Because of concerns about the systemic hyperinsulinemia that invariably develops with systemically drained pancreas transplants, portal venous drainage is also utilized (Fig. 40-5). As 50% of insulin is removed with the first pass through the liver, systemic drainage leads to elevated peripheral insulin levels, which is not observed following portal venous drainage. Since hyperinsulinemia has been associated with dyslipidemia and accelerated atherosclerosis, portal venous drainage theoretically ought to decrease cardiovascular risk compared with systemic drainage.⁶⁴ Portal drainage is associated with stimulation of the IGF-I/GH axis, contributing to glucose control despite lower insulin levels.⁶⁵ However, despite a nearly 10-year experience with the procedure, no effect on cardiac morbidity or mortality has been shown, and graft and patient survival are essentially equivalent.⁶⁶⁻⁶⁸

Although the type of venous drainage typically depends on the preferences of individual surgeons or transplant centers, the decision to perform portal or systemic drainage may also depend upon the anatomy of an individual patient. Patients with multiple previous abdominal operations or who have a thickened mesentery may be more suited for systemic venous drainage. Alternatively, patients who have had multiple transplants or other operations on the iliac vessels may be candidates for portal venous drainage.

For portal venous drainage the superior mesenteric vein is dissected out just below the transverse mesocolon.⁶⁹ The right common iliac artery is almost completely dissected. An end-to-side anastomosis of the donor portal vein to the recipient superior mesenteric vein is performed with the duodenum oriented superiorly and the tail pointed inferiorly. The iliac artery graft of the donor is then passed through a hole created in the small bowel mesentery, and anastomosed to the recipient common iliac artery.

Most centers currently use enteric exocrine drainage for simultaneous kidney/pancreas transplant and some centers use enteric drainage for all transplants including solitary pancreas transplantation. This shift to enteric drainage occurred as a result of the significant morbidity associated with bladder-drained pancreas transplants. Morbidity includes recurrent urinary tract infections, hematuria, chemical urethritis, severe bicarbonate wasting, and dehydration. Historically, approximately 25% of individuals who receive a bladder-drained pancreas transplants require enteric conversion because of persistent complications,⁷⁰ but an additional percentage endure significant morbidity early after transplant. The major advantage of bladder drainage is the ability to monitor urinary amylase, a decrease in which can be associated with rejection. This can be helpful in solitary pancreas transplants, but is not as important for simultaneous pancreas/kidney transplants where graft function may be monitored by serum creatinine. Improved immunosuppression and an increased utilization of biopsy to diagnose rejection have led to a decreased reliance on urinary amylase.⁷¹

Enteric drainage is achieved by creating a side-to-side or end-to-side anastomosis of donor duodenum to recipient jejunum. This may be a loop of jejunum, or a Roux-en-Y configuration may be created. For bladder drainage a side-to-side anastomosis between the donor duodenum and the bladder is performed. Enteric drainage is always used for pancreas transplants with portal venous drainage because the orientation of the pancreas precludes anastomosis of the duodenum to the bladder.

If a simultaneous kidney-pancreas transplant is performed, the kidney transplant is usually placed in the left iliac fossa. The anastomoses, as with a kidney transplant via a retroperitoneal incision, are typically to the external iliac artery and external iliac vein. The kidney is typically placed in an intraperitoneal location, which increases the potential for torsion of the kidney on its vascular pedicle compared with kidney-alone transplants which are usually placed in a retroperitoneal location. Some surgeons prefer to raise a retroperitoneal flap to place the kidney retroperitoneally after implantation. Advantages to this approach include improved percutaneous access should biopsy be required, and a decreased risk of postbiopsy hemorrhage.

Following revascularization of the pancreas, attention is paid to bleeding from the pancreas which can be quite brisk. This is controlled with ties or suture ligatures. Since thrombosis is a common complication of pancreas transplantation, anticoagulation in the perioperative period is frequently employed, particularly for solitary pancreas transplantation. Thrombosis is less frequent in simultaneous pancreas-kidney transplantation, where uremic platelet dysfunction is protective. The extent of anticoagulation may range from the intraoperative administration of heparin prior to clamping of

vessels, followed up by low-dose heparin infusion and warfarin anticoagulation, to more conservative approaches such as the use of low-dose heparin for a limited interval postoperatively, or the use of aspirin or other antiplatelet agents. Hypercoagulability states may predispose to graft thrombosis in a significant number of individuals, although definitive data are lacking; anticoagulation is individualized based on risk.⁷² Whatever the approach, patients should be monitored for bleeding, since as many as 10% of patients experience postoperative hemorrhage requiring reoperation.⁷³

Figure 40-5. Back-table preparation of the pancreas. Before transplantation, the pancreas must be prepared in a slush-filled basin to maintain cold preservation. Preparation includes unifying the arterial blood supply of the pancreas by anastomosis of the donor external iliac artery to the superior mesenteric artery and the donor internal iliac artery to the splenic artery. The donor common iliac artery is used for anastomosis to the recipient iliac artery. During back-table preparation, donor splenectomy is performed.

Following revascularization serum glucose levels are obtained hourly. It is common for the blood glucose to decline significantly following revascularization, and it is not uncommon for it to fall to normal levels soon after the patient's arrival in the recovery room. At some point intravenous fluids should be converted to dextrose-containing solution in order to prevent hypoglycemia. Pancreas transplant recipients with enteric drainage require only maintenance fluid with consideration of third-space losses. Simultaneous kidney-pancreas transplant recipients may require the additional fluid replacement that would be administered following kidney transplantation alone. Individuals who receive bladder-drained pancreas transplants require replacement of pancreatic exocrine losses, which can be quite profound in the early postoperative period.

Immunosuppression

7 Immunosuppression for pancreas transplantation is similar to that for kidney transplantation. The immunogenicity of a pancreas transplant is considered to be greater than the majority of solid-organ transplants because of the extensive lymphoid component of the gland. In addition, the difficulty in diagnosing rejection compared to other solid-organ transplants makes the choice of immunosuppression more significant for pancreas transplants. Most centers use some forms of triple maintenance therapy utilizing a calcineurin inhibitor, an antiproliferative agent, and steroids, although steroid-free regimens are becoming more common. According to data from the Scientific Registry of Transplant Recipients, 92% of kidney-pancreas recipients in 2012 received tacrolimus as maintenance therapy, compared to only 3.5% who received cyclosporine.⁵⁰ Mycophenolate mofetil is the antiproliferative agent of choice in pancreas transplantation; the use of sirolimus declined from a peak of 19% in 2001 to 7% in 2012. The use of steroids for pancreas transplantation, while still much lower than prior to 2000, increased from 61% in 2007 to 68% in 2012.

The use of induction therapy to inhibit lymphocyte function is common. Several large randomized multicenter trials utilizing either T-cell-depleting antibody induction (OKT3, ATGAM, and thymoglobulin) or interleukin-2 (IL-2) receptor antibody inhibition (daclizumab and basiliximab) showed a reduction in the incidence of acute rejection but failed to demonstrate a significant effect on patient or graft survival.^{74,75} Despite this modest impact on overall graft outcome, 89% of kidney-pancreas transplant recipients received induction therapy in 2012, 79% T-cell-depleting agents, and 12% IL-2 receptor antibody.⁵⁰ The International Pancreas Transplant Registry (IPTR) has demonstrated a lower risk of pancreas graft loss in all categories of pancreas transplantation with the use of tacrolimus, and also demonstrated similar associations with the use of mycophenolate mofetil.⁵⁶ Consistent with the multicenter trials, IPTR analyses also fail to demonstrate a beneficial effect of induction therapy on patient and graft survival.

Several groups have reported excellent intermediate-term patient and graft outcomes utilizing steroid minimization protocols.^{76–78} These protocols generally employ an induction agent (usually a depleting T-cell antibody), tacrolimus, and either MMF or sirolimus. Steroids are given for a maximum of 3 days. These steroid minimization protocols, as in kidney transplantation, aim to avoid the significant short- and long-term side effects associated with corticosteroids. Regimens employing maintenance monotherapy have also been successfully employed, although based on registry data, these appear to be falling into disfavor.^{50,79}

Complications

Thrombosis of the pancreas transplant is the most common cause of graft loss in the early postoperative period, occurring in 5% to 10% of transplants. Why pancreas transplants are more prone to thrombosis than other solid-organ transplants is uncertain. The most likely mechanism is that ischemia reperfusion injury in the pancreas, characterized by the release of cytokines and activation of pancreatic enzymes, leads to accelerated injury and a procoagulant state. Diabetic patients have impaired fibrinolysis and are, therefore, relatively hypercoagulable. The relatively low venous flow through the portal vein, which leads to diminished flow velocity, may be contributory. Thrombosis is slightly more common in solitary pancreas transplantation than in SPK, probably due to the absence of uremic platelet dysfunction present in SPK recipients. The risk of thrombosis has been associated with donor factors such as older patient age, renal dysfunction, cold ischemic time, body mass index, DCD status, and cerebrovascular cause of death.^{55,80,81}

Pancreas transplant thrombosis is usually heralded by a sudden rise in blood glucose in a pancreas that was previously functioning. Confirmation of the diagnosis is usually obtained with duplex ultrasound. Although anecdotal reports have described successful surgical and angiographic thrombectomy or thrombolysis in restoring flow to the pancreas,^{82,83} the usual treatment is removal of the infarcted pancreas. While this usually occurs immediately after diagnosis, some centers opt to relist the patient urgently and wait until another pancreas transplant becomes available. Depending on the waiting time for another pancreas, the added morbidity of delaying the graft pancreatectomy is usually not significant. In contrast, asymptomatic thrombosis, whether partial or even complete, has been successfully managed with anticoagulation, especially if late in onset.^{84,85} Because of the high risk of thrombosis, some degree of anticoagulation is frequently employed after pancreas transplantation.⁸⁶ It is likely due to these efforts and improvements in immunosuppression that the thrombosis rate for simultaneous pancreas–kidney transplants has decreased to less than 5% for simultaneous pancreas–kidney transplant and to less than 10% for isolated pancreas transplants (Fig. 40-6).

Bleeding is another frequent cause for reoperation in the early postoperative period. Because of the large number of vessels that enter and exit the pancreas, bleeding following reperfusion is not unusual. While readily controllable, it is not uncommon for bleeding points to emerge later in the procedure, and postoperatively. This can be minimized by meticulous attention to ligating vascular structures during pancreas procurement. The use of anticoagulation in the perioperative period, as described above, adds to the bleeding risk. Pancreas transplant recipients are monitored carefully in the early postoperative period for signs and symptoms of intra-abdominal hemorrhage.

The other major early complication is leak from the donor duodenum. Duodenal leaks occur in approximately 5% to 10% of cases, usually 1 to 2 weeks after the transplant.⁸⁷ A leak may present as fever, abdominal pain, leukocytosis, lower abdominal tenderness, and persistent ileus. The diagnosis may be supported by the finding of a focal fluid collection near the head of the pancreas on CT scanning or ultrasound. Alternatively, diffuse peritonitis may reflect disseminated contamination. For bladder-drained pancreas transplants, the diagnosis may be made by cystography.

Figure 40-6. Technical graft failure rates for U.S. pancreas transplant recipients by year. (Data from Scientific Registry of Transplant Recipients. 2013 Annual Report. Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2015).

The management of a suspected duodenal leak is operative. Peripancreatic sepsis or abscess can occur in the absence of a frank duodenal leak. This is caused by the growth of organisms transmitted into the peritoneal cavity during performance of the duodenal anastomosis. The peritoneum should be lavaged and all necrotic debris removed. If a leak is present it is usually at the stapled end of the duodenum rather than at the anastomosis. The likelihood of success for repair of a duodenal leak depends on the viability of the duodenum at the point of the leak, the patient's overall hemodynamic stability, and the degree of surrounding inflammation. Usually one attempt at repair is made, but failure may necessitate removal of the pancreas in order to control life-threatening sepsis. Some surgeons have adopted a practice of managing leaks from duodenal enteric anastomoses by conversion to bladder drainage. This minimizes the risk of recurrent contamination of the peritoneal cavity with enteric contents and allows for Foley catheter decompression of the duodenum, but has the morbidity associated with bladder drainage. Occasionally a fluid collection or leak which presents late and without systemic sepsis can be treated with percutaneous CT-guided drainage.⁸⁸ In addition, drainage of infection without primary repair of the duodenal leak has been successfully employed in situations where inflammation is so profound that the leak could not be primarily repaired. However, the morbidity associated with these duodenal fistulas dictates that these options be employed only when definitive repair is not possible.

In contrast to renal transplantation, the complications of pancreas transplantation can be severe and life threatening if not properly managed. Even in the most experienced centers, occasional patients who suffer extended intensive care unit stays and even death are not unusual. This is a consequence of both the tenuous medical status of longstanding diabetics and the substantial morbidity of pancreas transplant complications. Therefore, given the limited survival benefit of pancreas transplantation, particularly compared with kidney transplantation, patients should be counseled frankly about the potential magnitude of these complications so that they have a realistic expectation of outcomes. Even with honest discussion and informed consent, most individuals will elect pancreas transplantation, and many will pursue multiple pancreas transplants even with a history of significant complications from previous pancreas transplants.

Diagnosis and Treatment of Rejection

The timely and accurate diagnosis of pancreas transplant rejection is one of the most important and challenging aspects of posttransplant management. As with kidney transplant rejection, pancreas rejection, whether acute cellular rejection or antibody-mediated rejection, is associated with inferior graft survival.⁸⁹ Furthermore, both pre- and posttransplant donor-specific antibody (DSA) are associated with antibody-mediated rejection and reduced pancreas and kidney graft survival.^{89,90} The incidence of pancreas rejection is about 20% to 25% in the first 2 years.⁵⁰ Therefore, the implications of delayed or missed antirejection treatment can be profound.

There is no single laboratory abnormality capable of diagnosing rejection. Amylase and lipase serum levels are commonly elevated, and can arouse suspicion, but are not specific. Hyperglycemia is also nonspecific, and if due to rejection occurs late, signifies significant pancreatic endocrine injury and has a dismal prognosis. While imaging modalities including ultrasound may identify abnormalities in parenchyma or perfusion, they are neither sensitive nor specific.⁹¹ Hence, the diagnosis of rejection is best made with histologic examination of a pancreatic biopsy specimen.⁹² The pancreas graft in SPK

transplants may be monitored by following the serum creatinine, as the concordance rate for rejection between kidney and pancreas grafts is believed to be high, although isolated pancreas rejection clearly occurs.^{93,94} Improvements in the outcome of solitary pancreas transplants are attributable to improvements in overall quality of immunosuppression, and to more accurate diagnosis and treatment of pancreas rejection.

The technique of pancreas transplant biopsy has evolved over the years. In the era of bladder-drained pancreas transplants, cystoscopic biopsy of both the pancreas and transplant duodenum was common.⁹⁵ As more enteric-drained pancreas transplants have been performed, a greater reliance on percutaneous biopsy has developed, using either ultrasound or CT-guided techniques.⁹⁶ Laparoscopic-assisted or open pancreas biopsy may be utilized for patients whose pancreas transplant is not accessible to percutaneous approaches, although the need for operative biopsy is decreasing as the percutaneous procedure has become more routine.⁹⁷ Enteroscopic biopsy has been described, and a high jejunal anastomosis can facilitate utilization of this method.⁹⁸ The indications for pancreatic biopsy include hyperamylasemia, hyperlipasemia, hyperglycemia, or unexplained pain in the vicinity of the pancreas transplant. The differential diagnosis includes pancreatitis, cytomegalovirus (CMV) infection, and toxicity from calcineurin inhibitors and, in the early postoperative period, peripancreatic infection. The histologic grading system developed at the University of Maryland for determining rejection grade in pancreas biopsies is generally used (Table 40-3).⁹⁹ Indeterminate rejection may be treated with increases in calcineurin inhibitor dose or pulse corticosteroids. More substantial rejection is generally treated with depleting antilymphocyte antibody therapy, either OKT3 or Thymoglobulin.

As long-term survival of pancreas transplants becomes more commonplace, chronic rejection is emerging as an important problem.¹⁰⁰ Unfortunately, as with kidney transplantation, while newer agents have improved short-term survival by preventing acute rejection, improvement of short-term survival has not translated into improved long-term graft survival.¹⁰¹ Chronic rejection is histologically characterized as expansion of fibrous septa within the pancreatic parenchyma. This may progress to lobular atrophy or loss of both acini and β -cells. Although there are parallels to chronic allograft nephropathy, whether chronic calcineurin inhibitor toxicity contributes to chronic pancreas rejection is unknown.

Table 40-3 Diagnosis: Revised Banff Classification for Diagnosis and Grading Pancreas Allograft Rejection⁸⁶

Category	Findings
1. Normal	Absent inflammation <i>or</i> inactive septal, mononuclear inflammation not involving ducts, veins, arteries or acini. There is no graft sclerosis. The fibrous component is limited to normal septa and its amount is proportional to the size of the enclosed structures (ducts and vessels). The acinar parenchyma shows no signs of atrophy or injury.
2. Indeterminate	Septal inflammation that appears active but the overall features do not fulfill the criteria for mild cell-mediated acute rejection.
3. Acute T-cell-mediated rejection	Grade I/Mild acute T-cell-mediated rejection—Active septal inflammation (activated, blastic lymphocytes and $\pm$ eosinophils) involving septal structures: venulitis (subendothelial accumulation of inflammatory cells and endothelial damage in septal veins), ductitis (epithelial inflammation and damage of ducts), <i>and/or</i> focal acinar inflammation. No more than two inflammatory foci per lobule with absent or minimal acinar cell injury. Grade II/Moderate acute T-cell-mediated rejection (requires differentiation from AMR)—Multifocal (but not confluent or diffuse) acinar inflammation (≥ 3 foci per lobule) with spotty (individual) acinar cell injury and dropout <i>and/or</i> mild intimal arteritis (with minimal, $<25\%$ luminal compromise). Grade III/Severe acute T-cell-mediated rejection (requires differentiation from AMR)—Diffuse (widespread, extensive) acinar inflammation with focal or diffuse multicellular/confluent acinar cell necrosis <i>and/or</i> moderate or severe intimal arteritis, $>25\%$ luminal compromise <i>and/or</i> transmural inflammation—necrotizing arteritis.
4. Antibody-mediated rejection	Confirmed circulating donor-specific antibody (DSA)—Morphologic evidence of tissue injury (interacinar inflammation/capillaritis, acinar cell damage swelling/necrosis/apoptosis/dropout, vasculitis, and thrombosis). C4d positivity in interacinar capillaries (IAC, $\geq 5\%$ of acinar lobular surface). Acute AMR 3 of 3 diagnostic components—Consistent with acute AMR 2 of 3 diagnostic components. Requires exclusion of AMR 1 of 3 diagnostic components. Chronic active antibody-mediated rejection—Combined features of categories 4 and 6 in the absence of features of category 3.
5. Chronic allograft arteriopathy	Arterial intimal fibrosis with mononuclear cell infiltration in fibrosis.
6. Chronic allograft rejection/graft fibrosis	Stage I (mild graft fibrosis)—Expansion of fibrous septa; the fibrosis occupies less than 30% of the core surface but the acinar lobules have eroded, irregular contours. The central lobular areas are normal. Stage II (moderate graft fibrosis)—The fibrosis occupies 30–60% of the core surface. The exocrine atrophy affects the majority of the lobules in their periphery (irregular contours) and in their central areas (thin fibrous strands criss-cross between individual acini). Stage III (severe graft fibrosis)—The fibrotic areas predominate and occupy more than 60% of the core surface with only isolated areas of residual acinar tissue <i>and/or</i> islets present.
7. Islet pathology	Recurrence of autoimmune DM (insulitis <i>and/or</i> selective β -cell loss). Islet amyloid (amylin) deposition.
8. Other histologic diagnosis	Pathologic changes not considered to be due acute <i>and/or</i> chronic rejection. For example, CMV, pancreatitis, PTLN.

Recurrent Autoimmunity

Selective β -cell destruction in pancreas transplants may occur in a pattern similar to the insulitis seen in type 1 diabetes. This pattern is histologically distinct from cellular rejection. Although recurrent autoimmunity has been documented in both immunosuppressed pancreas transplant recipients and nonimmunosuppressed living donor recipients from identical twin siblings, well-documented case series have been infrequent. A variety of associations have been suggested with autoantibodies to glutamic acid decarboxylase (GAD-65) and islet cells (IA-2), but patterns of autoantibody expression have not proven reliable enough to establish their etiologic relevance or prognostic value.^{102,103}

Posttransplant Viral Infections

The higher level of immunosuppression given to pancreas transplant recipients compared with kidney transplant recipients, particularly with respect to lymphocyte-depleting induction therapy, places pancreas transplant recipients at risk for conditions known to be influenced by overall immunosuppressive exposure. While rates of CMV infection are generally higher than for kidney recipients, especially when the donor is known to carry the virus, the use of intravenous and oral ganciclovir has reduced the incidence of significant CMV-associated disease.^{104,105} The incidence of CMV disease may also be lower in those recipients receiving steroid-free immunosuppression.¹⁰⁵ Data are mixed with respect to the incidence of polyoma-associated, or BK, nephropathy, with some analyses suggesting a higher rate and other an equivalent incidence in SPK recipients compared with kidney-alone recipients.^{106,107} As with kidney-alone recipients, those SPK recipients with BK nephropathy have inferior kidney graft survival. Posttransplant lymphoproliferative disorder (PTLD), often associated with Epstein–Barr virus (EBV) infection, has a 5-year incidence of approximately 2%, which is similar to or higher than kidney recipients.^{108,109} Pancreas recipients with PTLD have a worse prognosis than other abdominal organ transplants recipients with PTLD.

Figure 40-7. Pancreas graft survival among adult pancreas transplant recipients, 2008. (Data from Scientific Registry of Transplant Recipients. 2013 Annual Report. Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2015).

Results of Kidney–Pancreas Transplantation

Current kidney graft survival at 1 and 5 years following SPK transplantation is 96% and 80%, respectively.⁵⁰ African Americans have historically had somewhat poorer 5-year graft survival than whites. Kidneys from older donors have the poorest graft survival; 5-year graft survival from donors older than 50 is 68% compared with approximately 80% from donors aged 11 to 34. As opposed to previous decades, 5-year kidney graft survival is not associated with HLA matching.

Pancreas graft survival at 1 and 5 years following SPK transplantation is 86% and 73%, respectively (Fig. 40-7). Worse 5-year graft survival is seen in African-American recipients compared with whites. Recipients with a previous transplant (kidney, pancreas, or both) have worse pancreas graft survival. As with kidney survival, there is no difference in 5-year pancreas graft survival with increasing levels of HLA mismatch.

Registry analyses demonstrate a mortality benefit of SPK transplantation compared with dialysis¹¹⁰ or deceased donor kidney transplantation alone.¹¹¹ These benefits diminish with higher-risk donors, particularly older donors.¹¹² Patient survival at 1 year and 5 years following SPK transplantation is 98% and 92%, respectively. Race, ethnicity, gender, and transplant center volume are not associated with decreased patient survival at 5 years, and patient survival has improved since 1995 but not appreciably in the past 10 years.⁵⁰

Results of Solitary Pancreas Transplantation

The 1-year pancreas graft survival for recipients of a PAK transplant has improved in the last 5 years, from 78% for PAK transplants performed in 2005 to 88% for transplants performed in 2011.⁵⁰ Graft survival for PAK at 5 years is currently 53%. One-year pancreas graft survival for PTA has improved in the last 5 years to 80%. The unadjusted graft survival for PTA at 5 years is 53%. Graft survival rates for PTA are better than PAK early, but the rate of graft failure in the long term is greater for PTA than for PAK. Patient survival for both SPK and PAK recipients is excellent, >90% at 1 year and >80% at 5 years.

8 Whether pancreas transplantation positively impacts patient mortality is controversial. One study reported that registrants on the waiting lists for PAK and PTA had better survival rates than recipients who underwent these procedures.¹¹⁰ Subsequently, another group, using a similar cohort but different analytical methods, reported better survival rates for recipients of solitary pancreas transplantation than registrants on the waiting list.¹¹³ These discrepancies are in part related to the differing methodologies used in the two studies with respect to deaths among those removed from the waitlist and also to variability in the year-to-year death rates on the waiting list. In contrast, both studies demonstrated a conclusive benefit for SPK recipients compared with remaining on the waiting list, which illustrates the importance of restoration of kidney function in this population, as with kidney-alone transplant. While opinions on the specific benefit of the pancreas transplant differ in light of the differing conclusions of these two studies, together the studies indicate any survival benefit conferred by the pancreas transplant is likely to be modest. In fact, most studies do not demonstrate a graft or patient survival advantage of SPK over living donor kidney transplant.^{111,114} The survival benefit of SPK over deceased donor kidney

transplant alone has been recently further quantified, and while statistically significant, the survival benefit was not considered clinically meaningful.¹¹⁵

Effect of Pancreas Transplantation on Secondary Complications of Diabetes Mellitus

There are data that clearly demonstrate the impact of pancreas transplantation on the course of secondary complications of diabetes. This could be predicted from the results of the DCCT, in that pancreas transplantation leads to a complete normalization of blood glucose and glycosylated hemoglobin levels that are vastly superior to those achievable by intensive insulin therapy. Therefore, it should not be surprising that pancreas transplantation has an impact on diabetic complications.

For example, while type 1 diabetic recipients of kidney transplants alone show typical findings of diabetic nephropathy following transplantation, SPK transplantation prevents the development of recurrent diabetic nephropathy.¹¹⁶ In addition, native diabetic nephropathy, including microvascular structural abnormalities has been demonstrated to reverse 10 years following successful isolated pancreas transplantation.^{117,118} These reports demonstrate convincingly that pancreas transplantation has a significant impact on diabetic nephropathy.

Effects on diabetic neuropathy have also been documented using nerve conduction studies, which are significantly improved following pancreas transplantation and SPK.¹¹⁹ Small corneal nerve fiber regeneration can be detected.^{120,121} Furthermore, clinical progression of diabetic neuropathy is significantly diminished compared to nontransplanted controls. However, no study has been able to demonstrate clinical improvement in existing diabetic neuropathy following transplantation. There is also an impact on autonomic neuropathy, with clinical improvement in epinephrine responses to hypoglycemia.¹²²

While the DCCT demonstrated a relationship between glycemic exposure and retinopathy, the effect of pancreas transplantation on retinopathy is only modest. While stabilization of moderate retinopathy has been demonstrated, long-term graft function (> 3 years) is required.^{123,124} Many pancreas transplant candidates have advanced retinopathy, and an effect has not been demonstrated in these individuals. Early acceleration of retinopathy, a phenomenon that has been noted with other methods of improving glycemic control, can occur in the first 6 to 12 months following transplant.

Pancreas transplantation also appears to have a modest impact of cardiovascular disease parameters. Despite the findings of the DCCT trial, assessment of the clinical impact of pancreas transplantation on the progression of cardiovascular disease lacks a definitive large scale study. Positive effects on lipid profiles, blood pressures and left ventricular ejection fraction have been demonstrated.¹²⁵ Some centers have demonstrated a positive impact on peripheral vascular occlusive disease, with others demonstrating a worsening of disease.^{126,127}

Regardless of the magnitude of objectively demonstrable benefits of pancreas transplantation, most recipients enjoy a dramatic improvement in quality of life.^{94,128,129} While many diabetics can adapt quite well to the dramatic glucose fluctuations and the associated morbidity of diabetes, the freedom from insulin and the avoidance of hyper- and hypoglycemia offered by a functioning pancreas transplant is a primary motivator for many recipients. The fervor with which many candidates pursue pancreas transplantation, especially retransplantation is an indication of the enormous benefit on quality of life for these individuals.

ISLET TRANSPLANTATION

Overview

9 The notion that insulin-producing β -cells could be physically separated from the pancreas and transplanted for the treatment of diabetes has long been recognized. Islet transplantation, as a cellular transplant, has significant potential advantages over whole-organ pancreas transplantation. Islet transplantation does not require an operative procedure.¹³⁰ In addition, the potential ability to preserve islets opens up possibilities with regard to distribution, allocation, transportation, and preparation of the islet recipient. Pretreatment of the graft to reduce immunogenicity or enhance survival and function is also possible.¹³¹ Recipients of successful islet transplants can have glucose metabolism and insulin secretion profiles that are close to normal, and maintain metabolic control in a manner equivalent to whole-pancreas transplantation.¹³² Although effects on long-term mortality and progression of diabetic complications are unproven, these benefits are also anticipated. From a long-range perspective, the development of islet transplantation sets some of the procedural, technical, and regulatory groundwork

for the eventual establishment of stem-cell derived β -cell transplantation. Furthermore, technologic advances in islet isolation for allotransplantation have been very successfully utilized in autotransplantation following pancreatic resection.

History

The development of islet transplantation was historically limited by poor graft survival. The first human islet allograft in a type 1 diabetic was performed in 1974 by the University of Minnesota.¹³³ The first islet autograft for the treatment of chronic pancreatitis was performed at Minnesota in 1977. Despite intense research in islet transplantation over three decades, until 2000 clinical islet transplantation met with minimal success.¹³⁴ While transplanted islets were capable of physiologic function, as evidenced by the 66% rate of insulin independence at 1 year in the 163 recipients of islet autografts from 1974 to 1995, even these recipients had significantly reduced functional β -secretory reserve.¹³⁵ Allotransplantation presented an even greater hurdle; in the 96 islet allograft recipients with type 1 diabetes from 1990 to 1994, C-peptide production and insulin independence at 1 year were 25% and 7%, respectively.¹³⁴ Of the 270 recipients until 1999, only six had achieved insulin independence for greater than 2 years.

The dramatic improvement in islet transplant outcome reported by the Edmonton Group in 2000 stimulated an increase in islet transplant activity.¹³⁶ Several important refinements in islet isolation and immunosuppression have been credited for the improvement in outcomes, including careful attention to pancreas procurement; minimization of cold ischemia time of the pancreas prior to isolation; avoidance of xenoproteins in the islet isolation process; and avoidance of steroids in the immunosuppressive regimen. The use of sequential infusions to achieve insulin independence has been critical to success for many centers. Subsequently, the enthusiasm that accompanied this success was tempered by the inability for many new centers to replicate the success of more established centers,¹³⁷ the disappointing long-term survival of the transplants,¹³⁸ and the costs associated with islet transplants, which are still not reimbursed by third-party payers and Medicare.¹³⁹ As a result, the volume of islet transplants has contracted in the past decade, as have the number of centers performing transplants.¹⁴⁰ Nevertheless, incremental improvement in efficacy and long-term outcomes in selected centers has resulted in sustained optimism that this procedure will ultimately be regarded as an alternative to pancreas transplantation.^{141,142}

Islet Isolation

The precise separation of the islets from the other tissues of the pancreas (exocrine cells, lymphatics, and vascular structures), is the most important determinant of successful islet transplantation. One of the limitations of islet isolation is the difficulty in getting a large number of high-quality islets, and consistent success in islet isolation is a combination of science, art, and experience. Although a variety of methods have been utilized, most currently employ some modification of the semiautomated method described by Ricordi in 1988.¹⁴³ This method combines mechanical distension with enzymatic digestion of the pancreas. After cleaning the pancreas of surrounding fat, the pancreatic duct is cannulated with an angiocatheter and the pancreas is distended and loaded with warm collagenase solution, which digests the pancreas.¹⁴⁴ The pancreas is then placed into a sterile chamber, which also contains a number of stainless steel or glass spheres. Additional collagenase solution is added, and the chamber is attached to a shaking apparatus or agitated by hand. The collagenase solution is recirculated and kept at 37°C as the chamber is agitated. Agitation of the chamber allows the spheres to continue to disrupt the structural integrity of the pancreas as it digests. Following digestion, the separation of islets from nonislet tissue is performed via density gradient centrifugation. After suspension in culture media, islets are counted and assessed for sterility, purity, viability, and functional capacity. As islet isolation in the United States is regulated by the U.S. Food and Drug Administration, stringent product release criteria are in place to ensure the quality of the transplanted islets.

The percentage of islet isolations that result in a transplantable preparation varies widely among centers, between 25% and 70%, and depends both on donor selection practices and the experience and expertise of the particular center. Many elements of the process, such as collagenase batch or type, gradient preparation, the use of culture and culture conditions, and additives to prevent islet loss, are not standardized. This variability reflects both the need for improvements in isolation efficiency and the art/science currently inherent in the process. The ultimate goal is to develop a reproducible process with enough fidelity to allow islet preparations to be biologically licensed, which appears to be a major barrier to federal funding for the procedure, which will be necessary for broader application.

Patient Selection

Candidates for islet transplantation are selected in a similar manner as for whole-organ pancreas transplantation. Islet transplantation is currently limited to adult type 1 diabetics with progressive diabetic complications who have failed intensive insulin therapy. Because islet transplantation remains experimental therapy with limited availability, the procedure is generally offered only to ideal candidates with minimal medical conditions other than diabetes. Most centers require evaluation and/or a period of treatment by an experienced endocrinologist specializing in diabetes. Candidates with coronary artery disease, chronic infections, including hepatitis B and C, or a prior solid-organ transplant are excluded. Nonuremic candidates must be free of renal insufficiency, due to concerns about aggravation of nephropathy by calcineurin inhibitors. Since efficacy of the islet transplant appears to be related to the number of islets transplanted per kilogram of recipient body weight, only lean (<70 kg or BMI <28) recipients are selected. Although most islet transplants are currently performed in nonuremic diabetics, islet transplants either concurrent with or following kidney transplantation are also performed.^{145,146}

Donor Selection/Procurement/Preservation

Donor selection for islet isolation differs from that for whole-pancreas transplantation in several respects. While the ideal donor for islet isolation is still young and healthy, the age and weight criteria are less stringent than for whole-pancreas transplantation. Donors greater than age 50, donors on vasopressors, and especially obese donors are all perfectly suitable for islet isolation. Since the ideal pancreas is easily distensible and digestible, fatty pancreata are felt to be especially suitable, whereas fibrotic pancreata are not. As previously mentioned, pancreata from older and obese donors (which are infrequently used for whole pancreas) are preferentially allocated for islet transplantation rather than for regional and national sharing for whole-pancreas transplantation.⁵²

The pancreas is procured in a manner similar to whole-pancreas transplantation. However, less attention to preservation of vascular structures is required. Attention is paid to surface cooling following flushing of preservation solution, and avoidance of pancreatic injury. A number of reports have highlighted the importance of a dedicated team trained in pancreas procurement in the success of islet isolation.^{147,148} Expanded use of the two-layer technique of pancreas preservation, using both standard preservation solution (UW solution or HTK) and oxygenated perfluorocarbon solution, has resulted in increased islet yields.^{149–152} The two-layer technique also permits the successful use for islet transplantation of pancreata subjected to prolonged cold ischemia as long as 18 hours. Success with pancreata from DCD has been reported.¹⁵³

Transplant Techniques

The portal circulation of the liver is currently the preferred site for islet transplantation (Fig. 40-8).¹⁵⁴ This can be performed by a minilaparotomy, with infusion of the islets into a peripheral mesenteric vein. However, most centers utilize interventional radiology techniques, avoiding both a surgical incision and general anesthesia. Percutaneous transhepatic portal vein catheterization is done under ultrasound and fluoroscopic guidance, with usually a small gauge (4-French) catheter. The islets are infused into the portal vein through the catheter by either gravity from an infusion bag or by hand injection, and the islets lodge in the hepatic parenchyma. Portal vein pressure is monitored intermittently throughout the procedure. Following infusion of the islets, hemostasis is usually achieved using a combination of coils and gelfoam. Recipients receive heparin in the islet preparation, systemically during the procedure, and in the perioperative period as prophylaxis against portal vein thrombosis, a now rare but serious complication.

Perioperative Care

Although islet transplantation is in theory an outpatient procedure, it is not uncommon for recipients to receive a few days of inpatient care for monitoring purposes. Immediately following the islet transplant, patients are maintained on bed rest for a short interval and monitored for bleeding. Liver function tests are monitored, and a liver ultrasound is frequently done to assess portal venous flow and to check for hematoma. It has been demonstrated that intensive glycemic control with insulin in the immediate posttransplant period is beneficial for islet function.¹⁵⁵ Hence, many centers will give insulin postoperatively to keep the serum glucose tightly controlled, in order to “rest” the islets. Additional adjuncts to prevent the instant blood-mediated inflammatory reaction (IBMIR), which results in early

islet loss and reduced β -cell mass in the recipient, may include antioxidants such as Vitamin E, etanercept (anti-TNF α antibody), anakinra (IL-1 β antagonist), reparixin (CXCR1/2 inhibitor), pentoxifylline, and others.¹⁵⁶

Figure 40-8. Islet transplantation. The pancreas is procured as a whole organ from the donor. The islets are isolated from the pancreas and are purified and infused into a cannula placed in a branch of the recipient's portal vein.

Immunosuppression

Current thinking focuses on the importance of the elimination of steroids from the immunosuppressive regimen, which typically uses basiliximab induction, and maintenance therapy with low-dose tacrolimus and sirolimus. Regimens employing mycophenolate mofetil and cyclosporine are also used, and thymoglobulin is an alternative induction agent. The best results for islet–kidney transplantation are cases where steroids are avoided or eliminated at the time of islet transplantation. While long-term effects of either the islet transplant or steroid elimination on kidney function are not known, steroid avoidance in kidney transplant recipients is now routine.⁵⁰ Regimens that avoid both steroid and calcineurin inhibitors have been successfully used.¹⁵⁷

Metabolic Control

Islet recipients show significant improvement in metabolic function and glycemic reserve, although hormonal counter regulation to hypoglycemia is diminished, actual hypoglycemic events are rare.¹⁵⁸ Data from the Collaborative Islet Transplant Registry show that at 1 year, approximately 59% of all transplant recipients were free of severe hypoglycemic events and maintained hemoglobin A1C (HbA1C) level of <6.5%. Of these 1-year responders, 69%, 54%, and 44% maintained this composite endpoint at 2, 3, and 4 years, respectively. Ninety-one percent of all recipients were free of severe hypoglycemic episodes at 1 year, and 80% at 4 years.¹⁴¹ Islet recipients also demonstrate a reduction in behaviors adopted in avoiding hypoglycemia and attenuation in concerns about hypoglycemic episodes.¹⁵⁹ Islet transplantation also results in improved insulin sensitivity mediated by effects at both the liver and skeletal muscle.¹⁶⁰ However, islet recipients have significantly diminished β -cell reserve than do recipients of whole-pancreas transplants, which may account for their reduced long-term survival.¹⁶¹ Acute insulin response to intravenous glucose is commonly used to determine islet engraftment, and is a robust early metabolic marker to predict return to insulin therapy.¹⁶² Analyses of the impact on diabetic complications and mortality await further experience.

Complications

Morbidity from islet transplantation is substantial but much less than for whole-pancreas transplantation. The most common serious complication is bleeding (1% to 5%). Most cases of bleeding can be managed nonoperatively with adjustments in anticoagulation, though occasionally laparotomy is

required. The side effects of immunosuppression, such as hyperlipidemia and mouth ulcers in sirolimus-containing regimens, are much more common and can significantly affect quality of life.¹⁶³ Renal insufficiency is an uncommon but serious consequence.¹³⁸ Transient elevations of portal venous pressure during islet infusion and elevations of liver function tests following infusion are common and usually well tolerated.^{164,165} However, reduction in liver perfusion during the islet infusion has been linked to premature graft failure.¹⁶⁶ The demonstration of late steatosis has raised concerns about chronic liver disease; to date this has not been reported.¹⁶⁷ CMV infection is rare. Mortality is virtually nil.

Sensitization and the development of posttransplant DSA, which was originally thought not to occur following allogeneic islet transplantation, are now recognized as a significant challenge. Recent experience has shown that most recipients showed DSA or autoantibody increases (de novo expression or titer increase) after islet transplantation. Recipients who have a posttransplant antibody increase have similar initial performance but significantly lower graft survival than patients without an increase.¹⁶⁸ Patients with complete graft loss who discontinue immunosuppression had significantly higher levels of anti-HLA antibodies than those with functioning grafts still on immunosuppression.¹⁶⁹ Ways to minimize sensitization in these recipients includes minimizing the number of islet donors used per recipient, and in the absence of donor-specific anti-HLA antibodies, repeating HLA mismatches with subsequent islet infusions.

Results

10 The short-term results of islet transplantation at high-volume centers are approaching that of whole-pancreas transplantation. The most successful centers achieve insulin independence rates of 80% to 90% at 1 year.^{136,170–171} In the Immune Tolerance Network multicenter trial of the Edmonton Protocol, success rates at the most successful centers (Edmonton, Minnesota, and Miami) were significantly higher than at the other centers.¹³⁷ However, long-term rates of insulin independence are worse than whole-pancreas transplants, but continue to improve. Overall, insulin independence at 3 years after transplant improved from 37% in the years 2003–2006 to 44% in the years 2007–2010, and the islet reinfusion rate was lower: 48% by 1 year in 2007–2010 versus 60% to 65% in 1999–2006. While in most centers less than 50% of recipients are insulin-free at 3 years, in experienced centers the 5-year insulin independence rate approaches 50% which approaches the graft survival of PTA.^{138,141,142}

One of the shortcomings of islet transplantation compared with whole-pancreas transplantation is the inability to reverse diabetes with the islets from one pancreas. Most of the recipients in the modern era have required two or more islet infusions to achieve insulin independence. However, some centers have successfully employed single-donor islet transplantation by utilizing careful donor and recipient selection, usually by transplanting islets from pancreata from large donors into small recipients.^{170,172–173} As long-term outcome appears to be related to β -cell mass, which is likely to be lower for single-donor infusions, these recipients may return to insulin or require retransplants earlier.¹⁷⁴ At the recipient level, administration of anti-inflammatory agents, whether nonspecific or directed at specific molecular targets, has become the mainstay of perioperative treatment. The ability to maximize the use of islets and minimize islet requirements and pancreas utilization for an individual recipient is critical if islet transplantation is to compare favorably with whole-pancreas transplantation.

Graft Failure

Graft failure appears to occur earlier than for whole-pancreas transplants. This may be related to a lower initial islet mass or the inability to histologically diagnose and treat islet rejection, since the islets are scattered about the liver parenchyma. As with pancreas graft failure, there is no true agreement on what constitutes graft failure, since recipients may require insulin yet make C-peptide and have superior metabolic control compared with pretransplant. Most outcome measures focus on insulin independence as the most stringent, and C-peptide production as the least stringent. Recent findings indicate that immunologic markers of rejection or recurrent autoimmunity, and metabolic indicators may identify recipients at risk for inferior outcomes and impending graft failure, although treatment algorithms based on these predictors are not standardized.^{162,168,175–176} A number of investigators have demonstrated the ability to label and identify islets in vivo in recipients in order to monitor functional islet mass—an example of this is ferucarbotran-labelling of islets, which enables their long-term noninvasive visualization by MRI and correlates with sustained C-peptide production.¹⁷⁷

Recipients with prior graft function who have returned to insulin are candidates for retransplantation. In fact, some centers have used transplanted islets from isolations where yields are insufficient for a primary transplant as retransplants, where the islet requirement may be less if there is still sufficient

residual graft function.

Alternative Methods

As the current method of islet allotransplantation has made great progress toward clinical application over a long period of time, other alternative methods have also advanced. There continues to be a great deal of interest in the use of encapsulated islets. These capsules can be made from a variety of materials designed to be permeable enough to permit the passage of insulin and glucose, but to isolate the islet from the immune system. Several pilot clinical trials in humans, with transplantation into the peritoneal cavity without immunosuppression have been reported, which confirms the safety of the procedure and the demonstration of graft function, if not insulin independence.^{178,179} No allo- or autoantibody has been detected in this small number of recipients. Human islets can also be shipped safely for long distances after encapsulation and culture without compromising viability and function.¹⁸⁰ The major barriers to graft function and longevity have been the tendency of the capsules to cluster and fibrose, which limits their efficacy.

Animal studies suggest that bone marrow precultured with human islets may enhance the survival and function of transplanted islets, thus significantly improving the therapeutic efficacy of islet transplantation.¹⁸¹ Other work has cotransplanted mesenchymal stem cells with islets, which may be beneficial for islet engraftment by promoting cell survival/angiogenesis and reducing inflammation.^{182,183}

THE FUTURE OF PANCREAS AND ISLET TRANSPLANTATION

Many challenges remain in determining the ideal insulin replacement therapy for type 1 diabetics. While the current allocation system designed to maximize whole-pancreas transplantation ensures the most efficient use of donor pancreata, improvements in the efficiency of islet isolation may require that further refinements be made to allocation policy. Current outcomes support the prioritization of whole-pancreas transplantation over islet transplantation, and sufficient long-term survival reproducible among a larger number of centers may be required before islet transplantation can move further into the mainstream. If this occurs, the reduced morbidity of islet transplantation may mean that a large number of candidates who are not surgical candidates for pancreas transplantation may be islet candidates in the future. Many centers have taken the philosophical step to offer islet transplantation primarily to diabetics who would not otherwise receive immunosuppression, that is, nonuremic diabetics. This is somewhat in contrast to PTA transplantation, which is offered to only the most exceptional candidates. Taken further, islet transplantation could theoretically be open to a large number of type 1 diabetics that would surely exhaust the limited supply of human donor pancreata. However, the experience gained by the development of islet transplantation would surely apply to technologies not affected by donor supply, such as islet xenografts or engineered β -cells, which could have a profound impact on the devastating effects of diabetes on the public health worldwide.

Head and Neck

J. Kenneth Byrd and Robert L. Ferris

Key Points

- 1 Squamous cell carcinoma (SCC) is the most common malignancy of the head and neck region. Tobacco, alcohol, and human papillomavirus are the major risk factors.
 - 2 A cystic neck mass in an adult represents a neck metastasis until proven otherwise, and should not be incised and drained.
 - 3 A multidisciplinary team should evaluate patients with a suspected head and neck tumor for treatment options.
 - 4 Functional reconstruction is equally important as oncologic resection in head and neck surgery.
 - 5 Patients with new hoarseness for more than 2 weeks should be evaluated by a physician capable of performing flexible fiberoptic laryngoscopy.
-

INTRODUCTION

The head and neck is a complex anatomical subsite, containing the major structures responsible for sight, hearing, smell, speech, and swallowing. Disorders of the head and neck can therefore cause detriment to quality of life by interfering with these functions. Knowledge of the anatomy of the region is crucial to treat patients who present with complaints involving the head and neck, whether benign or malignant. The following chapter will provide an overview of common presentations of head and neck disorders, including head and neck cancer, which accounts for over 50,000 cases per year.

PATIENT EVALUATION

1 As in any clinical evaluation, a careful patient history should be taken, paying particular attention to the timing of onset, severity, progression, and associated symptoms. [Table 41-1](#) lists some of the more common presenting signs and symptoms of head and neck cancer. Social history is of particular importance in head and neck patients, as tobacco and alcohol use synergistically increase the risk of head and neck squamous cell carcinoma (SCC).¹ The clinician should document type, frequency, and duration of use on any patient suspected to have a head and neck disorder. Sexual history may also be of some interest, as the number of oral sexual partners has been associated with an increased risk of HPV-related oropharyngeal cancer.²

On physical examination, the physician should proceed systematically through each area of the head and neck. Gross deformity, skin lesions, previous incisions or scars, and radiation sequelae should be noted. The physician should pay attention to any breathing difficulty, including stridor, stertor, and nasal obstruction.

Each mucosal subsite of the head and neck region should be thoroughly inspected ([Table 41-2](#)). A headlight or headlamp should be used to inspect the oral cavity, oropharynx, and larynx/hypopharynx (if indirect mirror laryngoscopy is performed). Dentures should be removed prior to bimanual examination of the oral cavity and oropharynx using tongue blades to check all mucosal surfaces.

Although some otolaryngologists prefer indirect laryngoscopy to visualize the larynx and hypopharynx, patients with large tongues and/or hyperactive gag reflexes may be difficult to examine. In the setting of possible malignancy, we recommend that all patients undergo flexible fiberoptic laryngoscopy, which provides excellent dynamic visualization and the ability to record images and video when coupled with appropriate equipment. Additionally, flexible or rigid endoscopy provides a more detailed view of the nasal cavity than anterior rhinoscopy. [Figure 41-1](#) demonstrates the view of the larynx provided by in-office stroboscopy.

The cervical lymph nodes should be palpated carefully, taking note of the location in levels I to V of the neck, as described by Robbins et al. (Fig. 41-2),³ as well as lateral and superior–inferior mobility. Pulsatility of the mass may suggest a vascular pathology, and should not be biopsied prior to imaging. The laryngeal and tracheal framework should be examined to determine any disruption to the normal architecture, as well as the position relative to the sternum. The thyroid gland should also be palpated as part of every head and neck examination, although this is addressed in a separate chapter.

In the neurologic examination, particular attention should be paid to the cranial nerves. In sinonasal pathology, hyposmia may be due to nasal obstruction, or alternatively due to direct involvement of the olfactory nerve. Extraocular movement abnormalities can result from orbital or skull base pathology. Temporal wasting or facial numbness may be a sign of perineural spread in the trigeminal nerve, and facial weakness or twitching in the setting of a parotid mass suggests malignancy. Ipsilateral vocal paralysis or impaired palatal elevation may suggest involvement of the vagus nerve, important to note in skull base paragangliomas. Preoperative shoulder weakness in the setting of lymphadenopathy may prompt the surgeon to counsel the patient about the need for radical neck dissection, as the spinal accessory nerve may be involved by tumor.

WORKUP

In the setting of an accessible tumor (e.g., oral tongue, tonsil) biopsy may be performed in the office under local anesthesia. In more distal subsites, operative direct laryngoscopy is required. For palpable salivary or cervical masses, fine-needle aspiration is easily performed without image guidance. In most patients with head and neck pathology, CT with contrast is the preferred imaging modality. MRI can be of value in some cases, such as when perineural spread is a concern, to evaluate for invasion of intrinsic tongue musculature in oral or oropharyngeal cancer, and for orbital and dural assessment. When malignancy is diagnosed, metastatic workup with PET/CT or chest CT should be performed in stage III/IV pathology.

Table 41-1 Differential Diagnosis of the Neck Mass

Congenital	Branchial cleft Vascular malformation Thyroglossal duct cyst Dermoid
Infectious	Tuberculosis Atypical mycobacteria Cat scratch disease Mononucleosis Odontogenic Sialadenitis
Inflammatory	Sarcoidosis Sialadenosis
Trauma	Hematoma Laryngocele
Neoplasm	Epithelial (SCC, melanoma, adenocarcinoma) Salivary Neurogenic Sarcoma Lipoma Lymphoproliferative

Salivary	Parotid Submandibular Sublingual Minor
Lateral skull base	Parapharyngeal space Infratemporal fossa Temporal bone

AIRWAY MANAGEMENT

Although the anesthesia team is primarily responsible for evaluating the airway, the surgeon should share some responsibility in patients with head and neck disorders. A number of patient factors have been described in the anesthesia literature as predictors of difficult laryngoscopy, including sternomental distance, Mallampati score, thyromental distance, and mouth opening.⁴ However, the head and neck surgeon will be more aware of the endoscopic airway anatomy as a result of preoperative imaging and laryngoscopy. Bulky supraglottic and oropharyngeal masses may lead to failure of mask ventilation and difficulty passing an orotracheal tube; lesions prone to bleeding may cause similar problems. Patients with fibrosis from prior radiation or chemoradiation may have impaired laryngeal excursion, in addition to trismus. In a prospective study of intubation in patients with head and neck pathology, one group found that prior radiotherapy, a diagnosis of cancer, and supraglottic or glottic subsite were predictive of airway difficulty.⁵ Indeed, it is imperative that the surgeon and anesthesiologist communicate about the airway plan prior to induction.

Figure 41-1. In-office stroboscopy demonstrates a normal larynx with glottis open. Stroboscopy allows for dynamic visualization of the mucosal wave and arytenoid movement.

Figure 41-2. The cervical lymph nodes are divided into six groups, or levels.

Figure 41-3. Tracheostomy. **A:** The incision for an elective tracheostomy is typically placed on a horizontal axis, approximately two finger breadths above the sternal notch. A vertical incision allows for less bleeding when the procedure must be performed emergently. **B:** The strap muscles are separated in the midline. The thyroid isthmus may bulge into the wound (**C**), necessitating inferior retraction or division (**D**). **E:** After the second tracheal ring is cleaned off, an inferiorly based flap (i.e., Bjork flap) is developed in the tracheal wall and sutured to the skin. This allows for easy access to the trachea while the tract is maturing.

In patients for whom difficulty is predicted, fiberoptic nasotracheal or orotracheal intubation may be safely performed with the patient spontaneously breathing with topical anesthesia and sedation. Alternatively, planned awake tracheotomy is an option in patients with severe obstruction and abnormal anatomy. Additionally, a tracheotomy kit should always be nearby for emergent cricothyrotomy or tracheotomy, should it be necessary. [Figure 41-3](#) demonstrates the typical sequence of steps in a tracheotomy.

INFECTIOUS

Pharyngitis and Abscesses

Acute pharyngitis is a common presentation in outpatient offices and the emergency department. Although group A streptococcus is a concern due to its potential complications, it accounts for only 10% to 15% of pharyngeal infections in adults; the majority are viral. Patients with fever, tonsillar exudates, absence of cough, and cervical lymphadenopathy are more likely to have bacterial pharyngitis, and should be tested for streptococcus and subsequently treated with amoxicillin, clindamycin, or a macrolide.⁶ Those without streptococcal pharyngitis may generally be treated with hydration and analgesics, although antibiotics may be indicated if atypical bacteria are suspected or if symptoms fail to improve.

The most common head and neck abscess is the peritonsillar abscess, which typically arises from untreated bacterial pharyngitis that leads to bacterial invasion of the parapharyngeal space if not drained. Patients typically present with throat pain, trismus, dysphagia and odynophagia, and a muffled voice. Physical examination reveals palatal and tonsillar bulging and uvular deviation toward the unaffected side. Imaging is often unnecessary but may be useful in equivocal cases. Drainage is performed at bedside after topical anesthetic spray and injected lidocaine or bupivacaine are used to anesthetize the area; trismus is often greatly improved after local is administered, facilitating drainage. An 18-gauge needle can be of use to localize the pus collection and plan the incision. An 11 or 15 blade is then used to make an incision, which is enlarged with a hemostat when the abscess is localized. Palpation of the tonsil with the hemostat or a cotton swab will express the remaining fluid (Fig. 41-4). Antibiotics with broad coverage (e.g., amoxicillin-clavulanate or clindamycin) should be prescribed for 10 to 14 days.⁷ Patients with a history of multiple peritonsillar abscesses should be considered for tonsillectomy.

Figure 41-4. Schematic representation of a peritonsillar abscess. Purulence develops between the tonsillar capsule and the superior pharyngeal constrictor muscle. As a result, the palate bulges and the tonsil is deviated medially. Inflammation in the region of the pterygoid muscles results in pain and trismus which may be significant.

In evaluating the patient with pharyngitis or a peritonsillar abscess, it is important to differentiate from epiglottitis. Patients may present similarly, with odynophagia, a muffled voice, and drooling. However, patients with acute bacterial epiglottitis are more toxic in appearance and have impending airway compromise. Plain film radiographs of the neck will display the “thumbprint” sign, or an edematous epiglottitis. If the patient is tolerant, transnasal flexible laryngoscopy can be used to confirm the diagnosis, but early securing of the airway in the operating room with tracheotomy or fiberoptic intubation is paramount.

Progression of odontogenic or pharyngeal infections can lead to deep neck space infections, as well. Early evaluation of the patient’s airway is paramount in deep neck infections, as they may rapidly progress, particularly in the immunocompromised (e.g., diabetics). Elective intubation is often required, and tracheotomy may be necessary in the setting of prolonged airway edema. Of particular concern are infections involving the floor of mouth, or Ludwig angina, which can quickly progress bilaterally, and cause airway compromise via posterior displacement of the base of tongue and trismus. In this setting, awake fiberoptic transnasal intubation may be attempted, but the surgeon should be prepared for awake tracheotomy. Infections in other neck spaces, including the Danger Space and Prevertebral Space, may spread quickly through the entire neck and cause rapid decompensation. Figure 41-5 lists the relevant deep neck spaces and paths of spread.

Operative intervention is usually required for deep neck infections, involving incision and drainage of the affected spaces. Copious irrigation with placement of suction drains is recommended to decrease the likelihood of reaccumulation, and reexploration is occasionally needed. Additionally, the odontogenic source of the infection should be addressed, ideally at the same time as the incision and drainage.

SINUSITIS

In the clinical setting, patients and caregivers often lump upper respiratory infection (URI) and “sinusitis” together. Indeed, the common cold virus is the most common infection associated with URI, which concomitantly involves the nasal mucosa and paranasal sinuses. Rhinosinusitis is therefore a better term than “sinusitis.” Rhinosinusitis is classified as acute, subacute, and chronic based on length of duration: less than 4 weeks, 4 to 12 weeks, and greater than 12 weeks, respectively.⁸

Figure 41-5. The deep spaces of the neck are distinct but interconnected compartments. Infections in any one of these may spread to involve other potential spaces and critical structures contained therein.

In the acute setting, it is important to differentiate between viral and bacterial rhinosinusitis, as both will present with fever, facial pressure and/or pain, nasal obstruction, and purulent or discolored nasal discharge. The American Academy of Otolaryngology-Head and Neck Surgery Clinical Practice Guideline for adult sinusitis notes that the vast majority of URIs are viral, and that bacterial rhinosinusitis should be suspected when symptoms persist after 10 days or worsen after a period of improvement.⁸

In the setting of presumed viral rhinosinusitis, patients should be treated with antipyretics and analgesics, and decongestants may be considered. For acute bacterial rhinosinusitis, amoxicillin was recommended as the first-line antibiotic in the 2007 guidelines; however, some now recommend amoxicillin-clavulanate for 5 to 7 days due to the increasing prevalence of resistance. A fluoroquinolone or doxycycline may be used as first-line treatment in patients with penicillin allergy.⁹

Surgery is not indicated for patients with acute sinusitis, unless orbital or intracranial involvement occurs, or in the setting of an immunocompromised patient who fails to respond to medical treatment. Similarly, imaging is recommended against, except in the aforementioned situations.⁸ However, *complicated* acute bacterial rhinosinusitis (Table 41-3) should be suspected when visual, mental status, or neurologic changes are present. Proptosis, chemosis, and periorbital edema may signify extension of infection into the orbit (Fig. 41-6). Contrasted CT is useful to determine the extent of disease, and may be complemented by MRI. Prompt consultation with ophthalmology and/or neurosurgery is warranted for these cases.

Acute, severe, evolving sinonasal complaints in the immunocompromised should raise concern for acute invasive fungal sinusitis, which is rapidly progressive and fatal if untreated. Patients with HIV, organ transplant, chemotherapy-induced neutropenia, and even uncontrolled diabetes mellitus may be susceptible. The organisms most commonly associated are from the *Aspergillus*, *Rhizopus*, *Mucor*, *Rhizomucor*, and *Absidia* genera.¹⁰ Nasal endoscopy should be performed at the bedside, and which will demonstrate pale or black, necrotic mucosa, typically involving the turbinates or septum. Frozen section biopsy is performed, rather than fungal cultures, as immediate diagnosis is imperative. The patient should be emergently and aggressively debrided to bleeding, vascularized tissue in the operating room, and concomitant consultation of an Infectious Disease specialist with initiation of antifungal drugs is advised. Reversal of the underlying immunocompromised state will improve prognosis, as well.

SIALADENITIS

Patients with sialadenitis present with acute onset pain in the parotid or submandibular areas. Patients who are debilitated, dehydrated, or have decreased salivary flow due to medications or other factors (e.g., previous radiation) are predisposed to salivary gland infection. Sialadenitis is a clinical diagnosis, based on reproducible pain with palpation of the affected gland(s), temporal course, and presence of purulence in Warthin or Stensen duct. Sialadenitis may be viral or bacterial, viral infections (mumps, HIV, etc.) having a tendency to affect multiple glands bilaterally. In acute bacterial sialadenitis, symptoms tend to present quickly, with purulent salivary secretions, tense, erythematous skin, fever, and leukocytosis. Most infections are caused by *Staphylococcus aureus*, although a variety of anaerobes and other oral pathogens may be cultured.¹¹

Figure 41-6. Contrasted coronal CT demonstrates a right-sided periorbital abscess (*asterisk*) arising in a child with acute bacterial ethmoid sinusitis. Urgent ophthalmologic consultation was obtained, which revealed increased intraocular pressure. The child was taken for endoscopic ethmoidectomy and orbital decompression.

Patients with uncomplicated sialadenitis should be treated with hydration, sialogogues, gland massage, and broad spectrum antibiotics if bacterial pathogens are suspected. If purulent saliva is noted, cultures may be sent. Worsening of symptoms after initiation of therapy should prompt consideration of abscess development, and imaging with ultrasound or CT should be performed. Recurrent or chronic salivary infections less often result from chronic infection, but rather structural or inflammatory disorders are more common. Connective tissue disorders, such as Sjogren syndrome, rheumatoid arthritis, and sarcoidosis may present with or develop salivary gland involvement, and should prompt consultation with a rheumatologist if suspected. Alternatively, a history of repeated episodes of sialadenitis or gland fullness can be due to sialolithiasis. Physical examination with palpation of the

submandibular and parotid ducts will reveal a palpable mass in cases with large, distal stones. These are best approached via intraoral cutdown on a lacrimal probe. However, smaller stones in the hilum or gland parenchyma may require imaging for diagnosis.

Although parotidectomy or submandibular gland excision has long been the treatment for such stones and strictures, improvements in fiberoptic technology have led to increasing adoption of sialendoscopy to implement gland-sparing interventions. A recent meta-analysis demonstrated a high proportion of success and low incidence in complications for patients undergoing sialendoscopy for obstructive disease.¹²

Finally, it is important to rule out neoplasia in patients with repeated salivary complaints, as tumors can cause transient obstruction, as well.

CYSTIC NECK INFECTIONS

2 A variety of head and neck infections may present atypically. While it is true that adult patients may *rarely* manifest infectious, cystic neck lesions, they should be presumed malignant until proven otherwise because of the high prevalence cystic lymph node metastasis in SCC, particularly the HPV-related disease (Fig. 41-7). Large, necrotic lymph nodes may become painful and swollen if hemorrhage or superinfection occurs, mimicking benign disease. It is important to note that incision and drainage of cancerous lymph nodes can hinder cure due to widespread tumor seeding.

Figure 41-7. Contrasted axial CT demonstrates a large, rim-enhancing mass involving the right level III and IV neck. Image-guided FNA was required to confirm HPV-related squamous cell carcinoma due to its cystic nature.

Algorithm 41-1

Algorithm 41-1. Workup of a Neck Mass in an Adult Patient.

With the previous caveats, the infrequent adult patient may present with atypical suppurative lymphadenitis or an infected, previously unrecognized branchial cleft cyst. If history and physical examination are suspicious for this, a limited trial of antibiotics may be initiated for 1 to 2 weeks to monitor for improvement. However, further workup, including complete physical examination, imaging, and fine-needle aspiration should be simultaneously undertaken to prevent delays in diagnosis. If a cystic neck mass is to be removed for diagnosis, a frozen section should be sent at the time of surgery, with completion neck dissection planned if SCC is present. [Algorithm 41-1](#) is a suggested approach to the adult with a lateral neck mass.

HEAD AND NECK NEOPLASMS

3 Patients with diagnosed head and neck tumor should be referred to a center with a multidisciplinary care team, including head and neck surgeons, radiation oncologists, medical oncologists, dentists, pathologists, radiologists, speech therapy, and social work. Treatment of head and neck neoplasms, whether surgical or nonsurgical, is likely to have an impact on speech, swallowing, and overall quality

of life, and anticipation and aggressive treatments of these aspects are crucial.

Table 41-4 Salivary Tumors

Benign	Malignant	Malignant Nonsalivary
Pleomorphic adenoma	Mucoepidermoid carcinoma	Lymphoma
Warthin tumor (papillary cystadenoma lymphomatosum)	Adenoid cystic carcinoma	Squamous cell carcinoma
Basal cell adenoma	Adenocarcinoma	Melanoma
Oncocytoma	Acinic cell carcinoma	
Hemangioma	Carcinoma ex-pleomorphic adenoma	
	Salivary duct carcinoma	
	Malignant mixed tumor	

SALIVARY

Salivary tumors, although rare, encompass a large number of benign and malignant pathologies (Table 41-4). The parotid is the most commonly involved gland, followed by minor salivary glands, the submandibular gland, and the sublingual gland. The majority of parotid tumors (~75%) are benign, the most common type being pleomorphic adenoma.^{13,14} However, there is an inverse relationship between frequency of gland involvement and rate of malignancy, with approximately 50% malignant pathology in the submandibular gland and up to 86% in the sublingual gland. The most common malignant tumor is mucoepidermoid carcinoma, followed by adenoid cystic carcinoma (ACC) and adenocarcinoma.¹³ Table 41-5 lists the T-staging for parotid malignancies according to the American Joint Committee on Cancer.¹⁵ Additionally, the parotid gland contains lymph nodes that receive lymphatic drainage from the scalp and face.

Salivary tumors commonly present with painless swelling, and the most typical location is in the parotid tail. However, tumors that arise in the deep lobe of the parotid (deep to the plane of the facial nerve) may extend into the parapharyngeal space and grow quite large before they are noticed, and may cause trismus or a pharyngeal bulge. Warthin tumors are associated with male gender and smoking, and may be bilateral or multifocal.¹⁶ Although most salivary tumors are benign, the presence of pain, trismus, or facial weakness should raise the clinician’s suspicion of malignancy.

In the setting of a small tumor without atypical symptoms, routine imaging is not necessarily required, as it is unlikely to change the surgical plan. When imaging is desired, CT is the mainstay of imaging due to its widespread availability and ease to obtain, although MRI can be useful to further delineate the extent of a mass and perineural invasion.¹⁷ Figure 41-8A,B demonstrates MRI characteristics of a pleomorphic adenoma on contrasted MRI.

Table 41-5 Staging of Major Salivary Gland Tumors

T1	<2 cm, without extraparenchymal extension
T2	2–4 cm, without extraparenchymal extension
T3	>4 cm, and/or with extraparenchymal extension
T4a	Involvement of skin, mandible, ear canal, or facial nerve
T4b	Encases carotid artery or invades skull base

Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springer.com

Fine-needle aspiration may be performed prior to surgery, based on surgeon preference. In practice, FNA may be useful for counseling patients in whom malignancy is found that a more aggressive surgery will be performed, or to avoid surgery in patients with inflammatory disease or lymphoid malignancies. However, the surgeon should be aware that the specificity for neoplasia and malignancy is high, however the sensitivity is lower and more variable for both.¹⁸

For benign lesions, partial superficial parotidectomy, taking just the tissue immediately around the tumor, is sufficient. Additionally, there is some evidence that, in experienced hands, extracapsular dissection without facial nerve identification may be equally effective and less morbid than superficial parotidectomy.^{19,20} Figure 41-9 demonstrates the steps performed in superficial parotidectomy with

facial nerve dissection.

Although “total parotidectomy” is typically recommended for malignancy, tumors may not be found to be malignant until final pathology.²¹ Furthermore, a total parotidectomy is very difficult to perform en bloc with preservation of the facial nerve, which should always be attempted if it is functional. In small tumors localized to the superficial lobe, a superficial parotidectomy with an ample cuff of normal gland is adequate. Tumors in the deep lobe require superficial parotidectomy for nerve identification and mobilization, which may cause a temporary paresis due to retraction. If tumor involvement necessitates nerve sacrifice, it should be reconstructed with a nerve graft.

PATHOLOGY-SPECIFIC CONCERNS

Pleomorphic adenoma is typically a well-encapsulated, enhancing, round lesion with a tendency to recur if incompletely excised or if there is tumor spillage. Malignant transformation occurs in approximately 6%, and increases with the length of observation.²² Although benign, up to 40% may have extension beyond the capsule (“tumor pseudopodia”), and incomplete capsules have also been described.²³ Therefore, it is generally recommended to take a cuff of parotid with the tumor, although the surgeon frequently finds that it is necessary to dissect the tumor capsule directly off the facial nerve. In cases that recur, surgical salvage is recommended, but radiation may aid in local control for patients who are not surgical candidates.

The prognosis and treatment of mucoepidermoid carcinoma and ACC are largely affected by histologic grade. Mucoepidermoid carcinoma is classified as low grade or high grade, and sometimes as intermediate grade depending on the grading system used. High-grade tumors tend to be more aggressive, recurring locally and metastasizing frequently. Similarly, ACC can be subdivided by histologic type, tubular being the most indolent and solid being the least. ACCs have a great propensity for perineural invasion, and therefore MRI should be performed to evaluate for nerve involvement, and frozen sections should be taken to clear nerves when they are involved.

Figure 41-8. Precontrast (A) and postcontrast (B) T1 MRI demonstrate a lobulated, heterogeneous mass within the right parotid gland just posterior to the retromandibular vein, consistent with a pleomorphic adenoma.

Figure 41-9. Superficial parotidectomy. **A:** The standard Blair incision or the cosmetically superior rhytidectomy incision may be employed. **B:** Branches of the facial nerve course between the superficial and deep lobes of the parotid. **C:** The main trunk of the facial nerve is identified 8 mm deep to the tympanomastoid suture line and at the same level as the digastric muscle. **D:** The nerve is then dissected distally, separating it from the substance of the parotid. **E:** Schematic representation of the relationship between the parotid and surrounding structures.

In general, ipsilateral neck dissection should be performed when lymphadenopathy is present, and in the N0 neck when there is high-grade pathology (salivary duct carcinoma, high-grade MEC, SCC, adenocarcinoma except for polymorphous low-grade adenocarcinoma, carcinoma ex-pleomorphic adenoma). Postoperative radiation should be used for stage III/IV disease, high-grade pathology, and perineural or extensive tissue invasion.

SINONASAL

Sinonasal tumors may present with vague symptoms, including nasal obstruction, epistaxis, decreased smell, or nasal discharge. Sinonasal tumors are rare, the most common being the benign inverted papilloma, with a yearly incidence between 0.2 and 0.6 per 100,000. However, there are over 70 pathologies that may involve the paranasal sinuses, over half of which are malignant.²⁴ The maxillary sinus is most commonly affected, followed by the ethmoid, sphenoid, and frontal sinuses.²⁵

Rigid endoscopy is required to evaluate the patient with a possible sinonasal tumor. Imaging of the sinuses and skull base with fine-cut CT is advisable prior to biopsy to evaluate for the integrity of the orbits, vasculature, and skull base, and to rule out odontogenic origin for maxillary sinus pathology. MRI is also valuable to assess for dural, intraorbital, and neural integrity. [Figure 41-10](#) is a contrasted T1 image of a sinonasal mucosal melanoma; MRI provides evidence that both the dura and the periorbita are intact, allowing for an endoscopic resection without craniotomy or orbital exenteration.

When possible, inverted papilloma should be resected in its entirety with drilling of its site of attachment to prevent recurrence, which may be as high as 70% without complete resection. The specimen should be sent for pathologic evaluation due approximately 10% risk of concurrent or delayed malignancy.²⁶ However, when tumor involves critical structures (optic nerve, carotid artery, etc.), they should be preserved and the patient followed closely.

For sinonasal malignancies, surgery is the mainstay for most lesions. SCC is the most common (40% to 50%), followed by adenocarcinoma and ACC.²⁷ “Round blue cell” tumors are less common, but represent several different pathologies, including esthesioneuroblastoma, sinonasal undifferentiated carcinoma (SNUC), neuroendocrine carcinoma, small cell carcinoma, mucosal melanoma, lymphoma, and various sarcomas. Rhabdomyosarcoma is most common in the pediatric population, and should be treated nonsurgically as primary therapy. Consultation with a head and neck pathologist is particularly important in patients with small blue cell tumors because high-grade pathologies (SNUC, small cell) tend to metastasize early and are also often treated with induction chemotherapy and radiation, or concurrent chemoradiation.

Figure 41-10. Postcontrast T1 coronal image of a sinonasal mucosal melanoma. MRI allows for the distinction between the vascular tumor and trapped secretions in the maxillary sinus (*asterisk*), and provides evidence that the periorbita is intact (*arrow*).

The widespread adoption of endoscopic sinus surgery in the 1990s has led to increasing comfort with minimally invasive techniques for sinonasal tumors. For inverted papilloma, the endoscopic approach is associated with a decrease in both recurrence rate and morbidity for inverted papilloma compared to open approaches.^{26,28} Similarly, evidence is building that T1 and T2 sinonasal tumors may be safely and effectively removed with the endoscopic approach, and that endoscopic resection may complement open surgery in combined cases.^{29,30}

HEAD AND NECK SQUAMOUS CELL CARCINOMA

SCC is the most common malignancy of the upper aerodigestive tract, and is associated with approximately 50% overall survival due to its aggressive nature and the tendency for patients to present with advanced stage. The staging criteria for the common head and neck tumor subsites are available in the American Joint Commission on Cancer or the National Cancer Comprehensive Network.^{15,31} Staging is based on the size and invasiveness of the primary tumor site, the number, size, and location of metastatic lymph nodes, and the presence or absence of distant metastases. Tables 41-6 to 41-9 list the TNM staging for the oral cavity, oropharynx, and larynx, which are grouped into an overall stage of I to IV (Table 41-10). Patients with AJCC stage I/II tumors may be treated with single modality therapy, radiation, or surgery. Those with stage III/IV will require multimodality treatment. It is of particular importance that higher-stage patients undergo multidisciplinary evaluation due to combination therapy and the need for aggressive functional rehabilitation after treatment.

Table 41-6 Oral Cavity Staging

T1a	<2 cm
T2	2–4 cm
T3	>4 cm
T4a	Invades bone, floor of mouth, inferior alveolar nerve, extrinsic tongue musculature, skin of face, or maxillary sinus
T4b	Involves masticator space, pterygoid plate, skull base, or surrounds internal carotid artery

T2	2–4 cm
T3	>4 cm
T4a	Invades larynx, extrinsic tongue musculature, medial pterygoid muscle, mandible, or hard palate
T4b	Involves lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, skull base, or surrounds internal carotid artery

Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springer.com

ORAL CAVITY

4 The subsites of the oral cavity include the lip, oral tongue, floor of mouth, hard palate, gingival mucosa and retromolar trigone, and buccal mucosa. Although patients are given the choice between surgical and nonsurgical treatment in most head and neck cancers, surgery is considered the primary treatment for oral cancer because of its ease of access and because of the risk of osteoradionecrosis of the mandible when high-dose radiation or chemoradiation is used in the region. Microvascular reconstruction is very important to restore the structure and function of the structures of the oral cavity to preserve speech and swallowing and minimize cosmetic deformity for larger tumors, and may require bone, soft tissue, or a combination of both.

Table 41-8 Larynx Staging

Supraglottis	
T1	Limited to one supraglottic subsite, with normal vocal cord mobility
T2	Tumor involves >1 subsite of epiglottis, or involves one adjacent mucosal subsite outside of epiglottis
T3	Vocal cord fixation, pre-epiglottic or paraglottic space involvement, or invasion of inner cortex of thyroid cartilage
T4a	Tumor invades outer cortex of thyroid cartilage, or invades tissues beyond larynx
T4b	Invasion of prevertebral fascia, mediastinal structure, or encasement of carotid artery
Glottis	
T1a	Tumor limited to one vocal cord, with normal mobility
T1b	Tumor involves both vocal cords, with normal mobility
T2	Extension into supraglottis or subglottis, or with impaired cord mobility
T3	Vocal cord fixation, paraglottic space involvement, or invasion of inner cortex of thyroid cartilage
T4a	Tumor invades outer cortex of thyroid cartilage, or invades tissues beyond larynx
T4b	Invasion of prevertebral fascia, mediastinal structure, or encasement of carotid artery

Site-specific considerations are important oncologically and functionally for oral cavity cancer. Lower lip carcinoma, which is most common and often due to sun exposure, has a very low incidence of occult cervical metastases (<15%), and may be observed in stage I/II with clinically negative nodes.³¹ In contrast, the upper lip has unilateral drainage, but a higher incidence of nodal involvement. Reconstruction of the lip may involve primary closure or local advancement for small lesions (<1/3 of length), and local or free flap reconstruction for larger tumors.³²

In oral tongue cancer, depth of invasion is clinically important. Very thin tumors (<2 mm) have a low likelihood to spread to regional lymphatics, in contrast to thick tumors (>8 to 9 mm). Although a definitive consensus has not been reached, many surgeons advocate elective neck dissection for patients with T1 tumors and depth of invasion >4 mm.³³ T1–T2 tongue tumors may be resected and closed primarily or with a skin or acellular dermis graft; larger lesions require microvascular reconstruction with enough bulk to allow for speech and deglutition. Similarly, small floor of mouth resections may be closed primarily, and grafts may be used when the floor of mouth musculature is preserved, but additional tissue is needed for larger tumors to prevent orocutaneous fistula when simultaneous neck dissection is performed.

STAGING

Table 41-10 AJCC Stage Grouping for Cancers of the Head and Neck (Excluding Thyroid and Nasopharynx)

Stage	Stage Grouping
0	Tis, N0, M0
I	T1, N0, M0
II	T2, N0, M0
III	T3, N0, M0 T1–T3, N1, M0
IVA	T4a, N0–1, M0 T1–T4a, N2, M0
IVB	T4b, Any N, M0 Any T, N3, M0
IVC	Any T, Any N, M1

Lesions of the retromolar trigone and buccal mucosa/space present a challenge due to early involvement of the muscles of mastication. Pterygoid and/or masseter may cause severe trismus, making preoperative examination and intraoperative exposure difficult. Marginal mandibulectomy (removal of the inner cortex) may be necessary when the tumor is attached to mandibular periosteum. Composite resection of a segment of mandible is required when the integrity of the bone is compromised on preoperative imaging, or when tumor has infiltrated via a tooth root or neural foramen. Microvascular osteocutaneous reconstruction has become the standard of care for most segmental defects due to the cosmetic and functional deformity of nonreconstruction (“mandibular swing”), and because of delayed hardware extrusion that occurs after several years with plating and soft tissue coverage alone.

NASOPHARYNX

Nasopharyngeal carcinoma (NPC) is an uncommon entity in most of the world, but is endemic to certain parts of Asia, most notably southern China. Although environmental and dietary factors play a role in the development of NPC, the most important causal factor is Epstein–Barr virus.^{34–36} The World Health Organization subclassifies NPC into three types: keratinizing SCC (I), nonkeratinizing SCC (II), and undifferentiated carcinoma (III).²⁴ Endemic NPC is 95% type III, which is associated with the best prognosis, and types I and II are more common in nonendemic areas.

Because the nasopharynx is not easily visualized, and because tumors tend to metastasize early, the most common presenting symptom is bulky lymphadenopathy. Of note, large lymphadenopathy is less prognostic in NPC than involvement of the supraclavicular fossa, which is reflected in a different nodal staging than for other head and neck subsites.¹⁵ Other possible complaints at presentation include nasal obstruction, speech changes, and hearing loss due to involvement of the eustachian tube. Cranial nerve palsies signify extension into the skull base, suggesting advanced disease.

Biopsy of the nasopharynx or lymph nodes to confirm NPC should be accompanied by imaging with CT and MRI to evaluate the skull base and infratemporal fossa. The primary treatment for NPC is nonsurgical, and concurrent chemoradiation has been shown to be superior to radiation alone in advanced disease.^{37,38} Surgery is reserved for failure of chemoradiation, and can be successful in patients with localized disease. In a large series of 312 patients undergoing salvage nasopharyngectomy, the 5-year overall survival was 62%,³⁹ although the majority of patients required a transfacial approach with maxillary disarticulation. With the advent of endoscopic techniques, some recurrences may be salvaged without traditional open approaches via the transnasal or transpterygoid approach, although control of the internal carotid artery is a concern.⁴⁰ Similarly, transoral robotic surgery has been reported for recurrences limited to soft tissue, although division of the soft palate is necessary, and there are no currently available robotic instruments that are suited to remove bone.⁴¹

OROPHARYNX

The oropharynx is comprised of the palatine tonsillar fossae and tonsils, base of tongue, soft palate, and posterior pharyngeal wall. While the incidence of head and neck SCC of other subsites has decreased with the prevalence of smokers in the United States, oropharyngeal cancer incidence has risen over the past two decades. This correlates with our understanding that the human papillomavirus, particularly subtypes 16 and 18, play a pathogenic role in squamous carcinoma of the oropharynx, and it is now

believed that HPV is responsible for approximately 80% of oropharyngeal cancer.⁴² In contrast to the poor prognosis of HPV-negative carcinoma of the oropharynx, HPV-associated cancer is associated with a favorable prognosis.^{43,44}

Figure 41-11. Transoral robotic surgery for a tongue base tumor. The retractor (*green arrow*) retracts the oral tongue. The lateral cut has been made 1 cm away from the tumor (*yellow asterisk*); the epiglottis (*black arrow*) is retracted to visualize the vallecula.

Although small T1–T2 tumors of the tonsils are often amenable to transoral excision,⁴⁵ radiation and concurrent chemoradiation have been used since the 1990s to treat less accessible and larger tumors due to equivalent effectiveness and decreased morbidity and mortality compared to the traditional open approaches, which involved transcervical, transpharyngeal, or transmandibular resection.⁴⁶ However, the rising prevalence of younger HPV-positive patients with favorable prognosis and the advent of minimally invasive approaches have led to increased interest in surgery as primary treatment, due to the long-term sequelae of radiation and chemotherapy.

Transoral laser microsurgery (TLM) and transoral robotic surgery have emerged in the past 10 years as techniques to treat T1–T3 tumors transorally with acceptable oncologic and functional outcomes.^{47,48} Advanced optics and instrumentation allow for complete tumor resection without requiring morbid open approaches (*Figs. 41-11* and *41-12*). Currently two prospective NCI funded trials, ECOG 3311 (HPV+ $n = 377$) and RTOG 1221 (HPV– $n = 144$), are underway to determine the role of surgical treatment for HPV positive and negative oropharyngeal cancer.⁴⁹

HYPOPHARYNX

The hypopharynx, comprised of the pyriform sinuses, postcricoid mucosa, and posterior pharyngeal wall below the level of the hyoid, is the area between the oropharynx and cervical esophagus. For the purposes of this chapter, cervical esophageal cancer will not be discussed. Cancer of the hypopharynx may present insidiously, with gradually increasing dysphagia, hoarseness due to laryngeal involvement, or ear pain referred through cranial nerves IX and X via Jacobson and Arnold nerves.

Compared to other subsites, the hypopharynx has a poorer prognosis, with an overall survival of only 30% to 35% in early stage cancer,⁵⁰ and a rate of distant metastases of up to 60%.⁵¹ Because of its proximity to laryngeal structures, hypopharyngeal cancer is typically treated nonoperatively, as most tumors would require removal of the larynx. Although induction chemotherapy followed by definitive radiation may be used in these patients, many institutions prefer concurrent chemoradiation, extrapolating the improved outcomes of concurrent CRT over sequential treatment in trials of other subsites. Small hypopharyngeal tumors of the posterior wall or pyriform sinus may be treated with transoral laser or robotic techniques,^{52,53} although bilateral neck dissection is required for regional control. Recurrent hypopharyngeal cancer may require total laryngectomy with partial pharyngectomy, or laryngopharyngectomy with microvascular reconstruction of the neopharynx.

Figure 41-12. Resultant defect from TORS resection, demonstrating the lingual artery in situ, which was coagulated later with bipolar cautery to prevent bleeding.

LARYNX

Tobacco and alcohol have a dose-dependent, synergistic carcinogenic effect on the epithelium of the larynx. The glottis, or true vocal cords, is the most common subsite involved, followed by the supraglottis (tip of the epiglottis to the laryngeal ventricle), and subglottis (1 cm below ventricle to the inferior border of the cricoid cartilage). In contrast to the respiratory epithelium of the rest of the upper aerodigestive tract, the glottis is comprised of stratified squamous nonkeratinizing epithelium overlying a complex lamina propria over the thyroarytenoid ligament and muscle. Due to the fibroelastic support of the conus elasticus and quadrangular membrane, early glottic tumors have a very low propensity for spread to regional lymph nodes, in contrast to the supraglottis and subglottis.

5 Early-stage carcinoma of the glottis (T1–T2) can be treated with single modality radiation or surgery, with approximately 90% cure for T1 and 75% for T2; early recognition and diagnosis at this stage therefore is key. Surgical treatment is performed via transoral resection, often using the CO₂ laser, which has no statistically significant difference in overall or disease-free survival or local control compared to radiation, although laryngeal preservation rates appear to be higher in the surgical group based on retrospective studies.^{54–56} Transoral resection of early glottic and supraglottic cancer has the advantage of requiring only one treatment, compared to the 6 to 7 weeks of radiation needed. However, supraglottic carcinoma has a high incidence of occult nodal metastasis, as well as bilateral drainage, and therefore planned bilateral level 2–4 neck dissection is recommended for patients who undergo surgery for the primary tumor.

For advanced laryngeal cancer (T3–T4), either surgery followed by radiation or concurrent chemoradiation may be offered, based on two randomized clinical trials. The so-called “VA Trial” demonstrated equivalent survival between surgery and radiation versus induction chemotherapy followed by radiation, with 64% laryngeal preservation in the nonsurgical arm.⁵⁷ This was followed by the RTOG 91–11 trial, which demonstrated the superiority of concurrent chemoradiation compared to radiation alone or after induction chemotherapy for laryngectomy-free survival and local control.⁵⁸ However, the 10-year follow-up to this study did not demonstrate an advantage of concurrent CRT versus induction chemotherapy and radiation in overall survival, local control, or overall laryngeal preservation.⁵⁹

For advanced stage laryngeal cancer, surgery generally involves total laryngectomy with bilateral lymphadenectomy, with local tissue or free tissue transfer as needed for pharyngeal reconstruction. This procedure functionally separates the airway from the digestive tract, but allows for effective verbal communication via esophageal speech, tracheoesophageal puncture with prosthesis, or electrolarynx. Open partial laryngeal surgeries, including supraglottic or supracricoid partial laryngectomy, may be used in selected cases, but have prolonged recovery of swallowing and airway protection.

Additional factors must be considered in choosing a treatment modality for patients with advanced stage laryngeal cancer. Radiation is less effective in cartilage and bone, and therefore thought to be inferior to surgery in T4 laryngeal cancer.⁶⁰ Additionally, patients who present with extensive paraglottic spread and vocal cord fixation will not regain function of the larynx with treatment, and are likely to remain tracheostomy-dependent if tracheotomy is performed prior to nonsurgical treatment.⁶¹ Similarly, patients with poor pretreatment swallowing are likely to worsen, and may become

permanently gastrostomy-dependent.

NECK DISSECTION

Head and neck SCC has a propensity to travel to the cervical lymphatics, the risk of which increases with T-stage. Pharyngeal tumors, especially those of the nasopharynx and hypopharynx, may present with a cervical neck mass. In cases when a patient presents with a neck mass for more than 2 weeks, the clinician should have a high suspicion for metastatic SCC, rather than an infectious or congenital etiology, and workup should entail imaging, fine-needle aspiration, and endoscopy.

In any patient presenting with SCC, consideration of therapeutic or elective treatment of the neck is imperative. In general, the cervical lymph nodes are treated with the same modality as the primary tumor; if surgery is undertaken for an oral cavity primary, for example, simultaneous neck dissection is performed. Similarly, the radiation oncologist will contour the treatment field to incorporate the relevant nodal basins in patients treated nonsurgically. Elective neck dissection or elective neck irradiation in the absence of clinically positive nodes is performed when the risk of occult nodal metastasis is greater than 15% (Table 41-11).

MANAGEMENT

Table 41-11 Indications for Elective Treatment of the Neck Based on Anatomic Locale and T Stage

Subsite	T Stages with >20% Risk of Occult Nodal Metastases
Oral cavity	T2, T3, T4
Oropharynx	T1, T2, T3, T4
Hypopharynx	T1, T2, T3, T4
Supraglottic larynx	T1, T2, T3, T4
Glottic larynx	T2, T3, T4

From Frank DK, Sessions RB. Management of the neck-surgery. In: Harrison LB, Sessions RB, Hong WK, eds. *Head and Neck Cancer: A Multidisciplinary Approach*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:189, with permission.

The techniques for neck dissections have evolved with time, initially being developed in the late 19th century as an en bloc procedure for removal of cervical lymphatics. Crile and Martin subsequently popularized the radical neck dissection, removal of the cervical lymphatics with sacrifice of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve. The modified radical neck dissection, removal of levels I to V with preservation of one or more of the three structures, then gave way to the idea of oncologic lymphadenectomy with decreased morbidity.⁶² Currently, selective neck dissection, the removal of the at-risk nodal basins with preservation of the SCM, internal jugular, and accessory nerve, is most commonly as the standard of care, as it preserves oncologic principles and minimizes morbidity.⁶³ The patterns of lymphatic drainage from each subsite are well described based on the publications of Lindberg and Shah.^{64,65} In general, dissection of levels II to IV is performed for cancers of the larynx, oropharynx, and hypopharynx, while levels I to III and possibly IV are addressed for oral cavity cancer (Fig. 41-13). Level V is rarely involved except in NPC and skin cancer.

Figure 41-13. Intraoperative photograph demonstrating the left neck after performance of a selective (supraomohyoid) neck dissection. Selective neck dissection is generally a low morbidity procedure. Vital structures such as the internal jugular vein (IJV), common carotid artery (CCA), and spinal accessory nerve (*large arrow*) are carefully preserved. In the context of an N0 neck, other nonvital structures such as the sternocleidomastoid muscle (SCM), external jugular vein (EJV) greater auricular nerve (GAN), cervical sensory rootlets (*small arrows*) and ansa cervicalis (*asterisks*) may also be spared.

Table 41-12 Complications of Common Head and Neck Surgeries

Tonsillectomy/Adenoidectomy
Hemorrhage
Velopharyngeal insufficiency

Hematoma/scroma
Marginal mandibular nerve injury
Lingual nerve injury
Neck Dissection
Spinal accessory nerve injury
Marginal mandibular nerve injury
Hypoglossal nerve injury
Great vessel injury
Chyle leak
Total Laryngectomy
Pharyngocutaneous fistula
Parathyroid injury with hypocalcemia
Hypoglossal nerve injury
Esophageal stricture

As in central neck dissection for thyroid cancer, a systematic, comprehensive approach should be used to perform neck dissection, rather than “node-plucking.” The boundaries for the common “lateral neck dissection,” encompassing levels II to IV, should extend from the digastric muscle’s insertion on the mastoid with the SCM superiorly to the plane of the clavicle inferiorly, and from the posterior edge of the SCM to the strap muscles anteriorly. The floor of dissection is the cervical sensory rootlets in level III and the fascia overlying the deep musculature in level II (levator scapulae) and in level IV (anterior

and middle scalenes). Care should be taken in level IV to avoid the phrenic nerve and brachial plexus, as well as the thoracic duct and right lymphatic duct. When level IB is included in the specimen, the marginal mandibular nerve must be elevated off the submandibular gland and protected to allow for safe resection of the gland and nodes along the facial vessels. Level V dissection requires identification of the spinal accessory nerve just below Erb point; it is then traced to its entry into the trapezius to protect it along its course.

COMPLICATIONS OF HEAD AND NECK SURGERY

Due to the intricate, complex anatomy of the region, surgery of the head and neck may be fraught with complications and morbidity. Although better understanding of anatomy and refined surgical techniques have fostered “functional” and “minimally invasive” approaches, complications occur, even in experienced hands. Salvage surgery after radiation or chemoradiation may be particularly difficult due to the extensive fibrosis that occurs. [Table 41-12](#) lists common and serious, rare complications of common head and neck procedures. When performing these procedures, the surgeon should be aware of critical structures in the area, and thorough discussion with the patient should be a part of the informed consent process.

SECTION D: ESOPHAGUS

Chapter 42

Esophageal Anatomy and Physiology and Gastroesophageal Reflux Disease

Daniel S. Oh and Steven R. DeMeester

Key Points

- 1 The esophagus can be considered to have distinct anatomical locations in the neck, chest, and abdomen with distinct physiologic and pathophysiologic considerations.
 - 2 The esophageal wall is composed of three distinct layers – the mucosa, submucosa, and muscularis propria. The mucosa is separated from the submucosa by the muscularis mucosae. Tumors lying within the mucosal layer may be managed endoscopically.
 - 3 The mucosal lining of the esophagus is squamous mucosa at birth. Repeated injury of the esophageal squamous mucosa with reflux may lead to metaplastic change to columnar mucosa such as cardiac mucosa, oxyntocardiac mucosa, or cardiac mucosa with intestinal metaplasia (goblet cells).
 - 4 Barrett esophagus is defined as having both an endoscopic columnar segment and a microscopic finding of cardiac mucosa with goblet cells or intestinal metaplasia.
 - 5 During a swallow, the peristaltic wave begins in the upper esophageal sphincter. The lower esophageal sphincter relaxes at the initiation of the swallow and remains relaxed until the peristaltic wave progresses down the esophageal body and through the lower sphincter.
 - 6 The lower esophageal sphincter retains its competence as a barrier to gastric contents by three factors: its length, its resting pressure, and its position.
 - 7 The function of the esophagus can be evaluated by endoscopy, radiology (fluoroscopy), and manometry. Measurement of acid exposure in the esophagus can be performed with ambulatory pH monitoring.
 - 8 The endoscopist should note three critical landmarks during an EGD: the squamocolumnar junction (SCJ), the gastroesophageal junction (GEJ), and the crura or hiatus.
 - 9 Preoperative functional assessment of the esophagus and lower esophageal sphincter are mandatory when considering antireflux surgery to tailor the operation to the appropriate circumstances of the patient.
 - 10 Ambulatory pH monitoring remains the gold standard for documenting gastroesophageal reflux and should be used to confirm the diagnosis of GERD.
-

ESOPHAGEAL ANATOMY AND FUNCTION

The esophagus is a muscular tube that starts as the continuation of the pharynx with the upper esophageal sphincter (UES) or cricopharyngeus and ends with the lower esophageal sphincter at the fundus of the stomach ([Fig. 42-1](#)). Knowledge of the anatomy of the esophagus and its relationship with other organs and structures is essential for the surgeon to evaluate the location of lesions seen by endoscopy, barium swallow study, or computed tomography (CT); to interpret esophageal function studies; and to safely expose the esophagus during surgery.

Cervical Esophagus

The cervical portion of the esophagus is approximately 3 to 5 cm long. It starts below the cricopharyngeus muscle and appears as a continuation of the inferior constrictor muscle of the pharynx. A space between the right and left inferior constrictor muscles posteriorly just above the cricopharyngeus muscle is an area of natural weakening and referred to as Killian triangle, the site where a Zenker diverticulum develops ([Fig. 42-2](#)). The beginning of the cervical esophagus is marked by the level of C6, and the end by the lower border of T1. The cervical esophagus curves slightly to the

left as it descends. Anteriorly, it abuts the trachea and larynx and can be dissected off both organs. Posteriorly, the cervical esophagus lies on the vertebral bodies in a prevertebral or retroesophageal space. This space is continuous with the retropharyngeal space superiorly and the posterior mediastinum inferiorly, which is the primary route of descending mediastinitis from oropharyngeal infections. Laterally, the omohyoid muscle crosses the cervical esophagus obliquely, and it is usually necessary to divide this to expose that portion of the esophagus. The carotid sheaths lie laterally, and the lobes of the thyroid and the strap muscles lie anteriorly. The recurrent laryngeal nerves lie in the grooves between the esophagus and the trachea. The right recurrent nerve runs a more lateral and oblique course to reach the groove and is more prone to anatomic variation. Although the surgical approach to the cervical esophagus may be from either side of the neck through an incision along the medial border of the sternocleidomastoid muscle, the left-sided approach is preferred to avoid injury to the more variable course of the right recurrent nerve.

Thoracic Esophagus

The thoracic portion of the esophagus is approximately 18 to 20 cm long (Fig. 42-1) and starts at the thoracic inlet. In the upper portion of the thorax, it is closely related to the posterior membranous wall of the trachea. This close relationship is responsible for the early spread of cancer of the upper esophagus into the trachea, and it may limit the surgeon's ability to resect such a tumor. Above the level of the tracheal bifurcation, the esophagus courses to the right of the aortic arch and the descending aorta and then deviates to the left, passing behind the tracheal bifurcation and the left main bronchus. In the lower portion of the thorax, the esophagus remains deviated to the left and passes anteriorly through the diaphragmatic hiatus. There are three natural areas of constriction in the thoracic esophagus: the cricopharyngeus or UES, the bronchoaortic constriction as it crosses behind the aortic arch and left mainstem bronchus, and the lower esophageal sphincter.

Figure 42-1. Anatomy of the esophagus.

Unlike the remainder of the gastrointestinal tract, the esophagus does not have a serosal layer and its strength is derived from its mucosa. The thoracic esophagus is covered only by parietal pleura, making this portion the weakest and the most common site of perforation in Boerhaave syndrome, usually on the left side where there is a lack of support from adjacent structures.

The azygos vein is closely related to the right of the esophagus as it ascends from the abdomen and then arches from its paraspinal position over esophagus and the right main bronchus to enter the superior vena cava.

The thoracic duct ascends behind and to the right of the distal thoracic esophagus between the azygos vein and aorta. At approximately the level of T5, it passes alongside the aorta and ascends on the left side of the esophagus to enter behind the junction of the left internal jugular and subclavian veins. Due to the possibility of disrupting the thoracic duct during its course across the mediastinum during an esophagectomy, ligation of the duct is generally performed low in the chest where it comes through the aortic hiatus.

Figure 42-2. Posterior view of cervical esophagus.

Abdominal Esophagus

The abdominal portion of the esophagus is approximately 3 to 6 cm long and consists of the abdominal portion of the LES. It begins as the esophagus passes through the diaphragmatic hiatus and is surrounded by the phrenoesophageal membrane, a fibroelastic ligament that arises from the subdiaphragmatic fascia as a continuation of the transversalis fascia lining the abdomen ([Fig. 42-3](#)). The upper leaf of the membrane attaches in a circumferential fashion around the esophagus about 1 to 2 cm above the level of the hiatus. The lower leaf of the phrenoesophageal membrane blends with the serosa of the stomach, and its end is marked anteriorly by a prominent fat pad, which corresponds approximately with the gastroesophageal junction. The lower esophageal sphincter is a zone of high pressure 3 to 4 cm long at the lower end of the esophagus¹ and does not correspond to any visible macroscopic anatomic landmark either on the external surface of the esophagus, nor in the endoscopic appearance of the mucosa. Its function is derived from the microscopic architecture of the muscle fibers. The esophageal hiatus is surrounded by the right and left crura, which together form a sling of diaphragmatic skeletal muscle around the esophagus that originates from tendinous bands attached to the anterolateral surface of the first lumbar vertebra ([Fig. 42-4](#)). The relative contribution of the right and left crura to this sling is variable. Posterior to the esophagus, the crura are united by a tendinous arch, the median arcuate ligament, which lies just anterior to the aorta.

Figure 42-3. Anatomy of the esophageal hiatus and relationship to the phrenoesophageal membrane.

Structure of the Esophageal Wall and Mucosa

The esophagus is composed of three primary layers – mucosa, submucosa, and muscularis propria. The mucosal layer is normally composed of nonkeratinized stratified squamous epithelium, as opposed to the stomach where columnar epithelium is present. In the distal aspect of the esophagus within the lower esophageal sphincter, repeated exposure of the squamous epithelium to gastric contents can result in metaplasia of esophageal squamous mucosa to a columnar epithelium called cardiac mucosa. This nomenclature was originally used to describe what was mistakenly thought to be the proximal stomach or cardia, but there is now convincing evidence that this is in fact metaplastic esophageal mucosa.² With further injury and exposure to refluxed gastric juice such as bile acids, cardiac mucosa may further transform into intestinal metaplasia or Barrett esophagus, characterized by the presence of goblet cells within cardiac mucosa. Alternatively, cardiac mucosa can also differentiate further to acquire parietal cells and is known as oxyntocardiac mucosa.³

A critical layer within the mucosa for determining the biologic behavior of a superficial cancer is the muscularis mucosa. This thin, poorly developed layer lies below the basement membrane and above the submucosa. It is often duplicated in patients with Barrett esophagus, and can lead to confusion during pathologic evaluation of the depth of tumor invasion in endoscopic resection (ER) specimens.⁴ The significance of the muscularis mucosa is that tumors confined to this layer rarely are associated with lymph node metastases, but once tumors penetrate through this layer into the submucosa the frequency of lymph node metastases increases substantially.

The submucosa is characterized by a rich lymphatic plexus that extends throughout the esophagus. Lymphatic collecting branches arise from within the submucosa and pierce the muscularis propria to communicate with regional lymph nodes and the thoracic duct outside of the esophagus. This network of lymphatics allow for significant longitudinal spread of esophageal cancers and a high rate of skip metastases. Clinically, tumor invasion beyond the muscularis mucosa into the submucosa is significant due to this lymphatic system, with the rate of regional lymph node metastases increasing from <5% with intramucosal tumors to 20% to 50% for submucosal tumors.⁵ Finally, the submucosa of the esophagus also harbors mucous glands that drain into the lumen. These glands are helpful for determining the true extent of the esophagus when metaplasia of the mucosa occurs.

The muscularis propria is composed of an inner circular layer and an outer longitudinal layer. The muscles are striated in the upper portion and transition to completely smooth muscle near the upper third of the esophagus. The longitudinal muscle layer courses down in an elongated spiral pattern, turning approximately 90 degrees as it descends to the stomach. The circular muscle layer is thicker than the longitudinal layer, which also takes on an elliptical or spiral orientation (Fig. 42-5). This arrangement of muscle is responsible for the wormlike drive of peristalsis.

Blood Supply, Lymphatics, and Innervation

The cervical portion of the esophagus receives its main blood supply from the inferior thyroid artery. The thoracic portion receives blood from the bronchial and esophageal arteries. Seventy-five percent of individuals have one right-sided and two left-sided bronchial arteries, and usually two esophageal branches arise directly from the aorta. There are rarely aortic branches directly to the esophagus in the lower half of the esophagus in the chest, allowing the surgeon to perform an en bloc dissection of all of the periesophageal tissue directly off the plane of the aortic adventitia from the right to the left pleural spaces. The blood supply of the abdominal portion of the esophagus comes from the ascending branch of the left gastric artery and from the right and left inferior phrenic arteries (Fig. 42-6). After the vessels have entered the muscular wall of the esophagus, branching occurs at right angles to provide an extensive longitudinal vascular plexus. The rich blood supply provided by this vascular plexus allows mobilization of the esophagus from the stomach to the aortic arch without causing ischemic injury.⁶

Figure 42-5. Endoscopic view of esophageal muscle layers during a peroral endoscopic myotomy (POEM) for achalasia. The endoscopic knife is lifting and cutting the circumferential circular muscle fibers, leaving the longitudinal muscle fibers intact.

Figure 42-6. Arterial anatomy of the esophagus.

The capillaries of the esophagus drain into a submucosal and periesophageal venous plexus, from which the esophageal veins originate. In the cervical region, the esophageal veins empty into the inferior thyroid vein; in the thoracic region, they empty into the bronchial, azygos, or hemiazygos veins; and in the abdominal region, they empty into the coronary vein ([Fig. 42-7](#)).

The lymphatic channels are located almost exclusively below the muscularis mucosa in the submucosa of the esophagus, constituting a dense and interconnected plexus with more lymph vessels than blood capillaries ([Fig. 42-8](#)). Lymph flow in the submucosal plexus runs in a longitudinal direction, and after the injection of a contrast medium, the longitudinal spread is six times that of the transverse spread. In the upper two-thirds of the esophagus, the lymphatic flow is mostly cephalad; in the lower third, it is mostly caudal. In the thoracic portion of the esophagus, the submucosal lymph plexus extends over a long distance in a longitudinal direction before penetrating the muscle layer to enter lymph vessels in

the adventitia. As a consequence of this nonsegmental lymph drainage, the lymphatic spread of tumor cells can extend for a considerable distance superiorly and inferiorly within the submucosal lymphatics before the cells pass through lymphatic channels in the muscularis and on into the regional lymph nodes. There is a high rate of skip metastases in esophageal cancer due to this arrangement. By contrast, the cervical esophagus has a more segmental lymph drainage into the regional lymph nodes, and as a result, tumors in this portion of the esophagus have less submucosal extension.

Lymph from the cervical esophagus drains into the paratracheal and deep cervical lymph nodes, whereas lymph from the upper thoracic esophagus flows mainly into the paratracheal lymph nodes. The lymph from the lower thoracic esophagus drains into the subcarinal and inferior pulmonary nodes. Lymph from the distal thoracic and abdominal portion of the esophagus drains into the parahiatal and perigastric nodes.⁷

Figure 42-7. Venous anatomy of the esophagus.

The parasympathetic innervation of the pharynx and esophagus is provided mainly by cranial nerve X or the vagus nerves. The constrictor muscles of the pharynx receive branches from the pharyngeal plexus, which is located on the posterior lateral surface of the middle constrictor muscle and is formed by pharyngeal branches of the vagus nerve, with a small contribution from cranial nerves IX and XI. The cricopharyngeal sphincter and the cervical portion of the esophagus receive branches from both the right and left recurrent laryngeal nerves originating from the vagus nerves (Fig. 42-9). Damage to these recurrent nerves interferes not only with the movement of the vocal cords but also with the function of the cricopharyngeal sphincter and the motility of the cervical esophagus, predisposing the patient to pulmonary aspiration on swallowing. The upper thoracic esophagus receives innervation from the left recurrent laryngeal nerve and both vagus nerves. As the right and left vagus nerves descend into the mediastinum, they join the outer surface of the esophagus. The esophageal plexus, which is formed by the branches of the right and left vagus nerves and thoracic sympathetic chain, lies on the anterior and posterior walls of the esophagus and innervates the lower thoracic portion.⁸ The branches of the plexus coalesce into the left (anterior) and right (posterior) vagal trunks.

Afferent visceral sensory fibers from the esophagus end without synapse in the first four segments of the thoracic spinal cord by a combination of sympathetic and vagal pathways. These pathways are also occupied by afferent visceral sensory fibers from the heart, which explains the similarity of symptoms in esophageal and cardiac diseases.

PHYSIOLOGY

To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a series of pumps and valves. In the pharyngeal segment, the tongue and pharyngeal muscle function as pumps, whereas the soft palate, the epiglottis, and the cricopharyngeus serve as the valves that regulate flow. In the esophageal segment, the esophageal body functions as the pump to propel the food bolus, whereas the lower esophageal sphincter serves as a valve to allow transport into the stomach and to prevent the flow of gastric contents back into the esophagus.

The Swallowing Mechanism

Swallowing can be started at will, or it can be reflexively elicited by the stimulation of the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. The afferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagal nerves. Once it is aroused by stimuli entering through these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through cranial nerves V, VII, X, XI, and XII and the motor neurons of C1 through C3. Discharges through these nerves always occur in a specific pattern and last for approximately 0.5 second. Little is known about the swallowing center except that it can trigger swallowing after a variety of different inputs. Once it is triggered, the swallow response is always a rigidly ordered pattern of outflow neurogenic impulses.

The act of alimentation requires the passage of food and drink from the mouth into the stomach. Food is taken into the mouth in a variety of bite sizes, after which it is broken up by the teeth, mixed with saliva, and lubricated. When food is ready for swallowing, the tongue, acting as a pump, moves the bolus into the posterior oropharynx and forces it into the hypopharynx (Fig. 42-10). Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. With the initiation of the swallow, the hyoid moves superiorly and anteriorly, thereby elevating the larynx and enlarging the retropharyngeal space. At the same time, the epiglottis covers the laryngeal inlet to prevent aspiration.

Figure 42-8. Lymphatic anatomy of the esophagus.

During swallowing, the pressure in the hypopharynx rises abruptly to 60 mm Hg as a result of the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the subatmospheric midesophageal or intrathoracic pressure (Fig. 42-11). This pressure gradient speeds the movement of food from the hypopharynx into the esophagus when the cricopharyngeus or UES relaxes. The bolus is both propelled by the peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus by this pressure gradient.

Critical to receiving the bolus is the compliance of the cervical esophageal muscle and the timing and degree of relaxation of the UES. Abnormalities of compliance and UES opening can result in pharyngeal dysphagia. During the transfer of the bolus from the mouth into the esophagus, the UES is mechanically pulled open. Elevation of the larynx by muscles attached to the hyoid bone pulls the UES open at the same time that relaxation of the UES is occurring. The active relaxation of the UES is caused by a reduction in the tone of the tonic constriction of the cricopharyngeus muscle, and it is dependent on a neurologically mediated reflex. This is an all-or-nothing event; partial relaxation does not normally occur. The UES closes within 0.5 second of the initiation of the swallow, with a postrelaxation contraction pressure that is approximately twice the resting pressure of 30 mm Hg. The postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 42-12). The high closing pressure and the initiation of the peristaltic wave prevent reflux of the bolus from the esophagus into the pharynx. After completion of the swallow, the pressure of the UES returns to its normal resting pressure.

The pharyngeal activity in swallowing initiates the esophageal phase of swallowing. Because of the helical arrangement of its circular muscles, the body of the esophagus functions as a worm-drive propulsive pump, and it is responsible for transmitting a bolus of food into the stomach. With the act of swallowing, the longitudinal muscle of the esophageal body shortens, thus enlarging the lumen to accept the bolus (the “on response”), after which the circular smooth muscle contraction forms the peristaltic wave (the “off response”). During the esophageal phase of swallowing, the bolus is moved into the stomach over a gradient of 12 mm Hg (i.e., from a negative intrathoracic pressure environment of -6 mm Hg to a positive intra-abdominal pressure environment of $+6$ mm Hg). Effective and coordinated smooth muscle function in the lower two-thirds of the esophageal body is important to allow this movement to occur.

Figure 42-9. Relationship of the esophagus to the vagus nerves and their branches.

The peristaltic wave generates an occlusive pressure that varies from 30 to 120 mm Hg. The wave rises to a peak in 1 second, remains at the peak for about 0.5 second, and then subsides in about 1.5 seconds. The whole course of the rise and fall of an occlusive contraction may occupy one point in the esophagus for 3 to 5 seconds.^{9,10} The peak of the primary peristaltic contraction moves down the esophagus at a rate of 2 to 4 cm per second and reaches the distal esophagus about 9 seconds after swallowing starts. The lower esophageal sphincter relaxes at the initiation of the peristaltic wave and remains open until the peristaltic wave passes through the body and into the sphincter muscle, and this

is followed by a distinctive postrelaxation contraction of the lower esophageal sphincter. A consecutive swallow after 20 seconds produces a similar primary peristaltic wave; however, if repetitive swallowing occurs sooner, the esophagus becomes unresponsive (*deglutitive inhibition*).

Figure 42-10. Overview of the act of swallowing.

Figure 42-11. Pressure profile of the esophagus in the neck, chest, and abdomen. (From Waters PF, DeMeester TR. Foregut motor disorders and their surgical management. *Med Clin North Am* 1981;65:1237, with permission.)

Figure 42-12. Overview of esophageal body peristalsis. (From Waters PF, DeMeester TR. Foregut motor disorders and their surgical management. *Med Clin North Am* 1981;65:1237, with permission.)

To be effective, peristaltic contractions must be of sufficient amplitude to occlude the esophageal lumen and sufficiently organized in a peristaltic waveform to propel a bolus toward the stomach. Low-amplitude contractions that do not occlude the lumen merely indent a semisolid bolus rather than propel it, and simultaneous contractions throughout the body of the esophagus result in splitting the bolus or propelling it orally which can be observed on a barium esophagram as bolus segmentation or cephalic escape.

Clinically, defects in peristalsis occur in three broad categories, depending on which major feature is the most impaired. First, there is a neural abnormality that results in the defective organization of the peristaltic wave; this is recognized by the presence of simultaneous contractions with a loss of the peristaltic sequence and results in typical primary motility disorders (e.g., diffuse esophageal spasm). The second category defect is evident when there is a reduction of the amplitude of the contraction but the peristaltic sequence remains; this is usually due to muscle damage and the formation of fibrous tissue within the muscle. Examples include end-stage gastroesophageal reflux disease (GERD) and connective tissue disorders such as scleroderma. The third category defect results from altered anatomy of the esophageal body. A loss in the efficiency of the peristaltic sequence can result when the esophagus is not anchored distally, as occurs with a large paraesophageal hernia (PEH); which can result in the appearance of an accordion esophagus on a barium swallow esophagram with ineffective clearance of barium.

Lower Esophageal Sphincter

The LES represents the barrier that confines the gastric juice to the stomach and protects the acid-sensitive squamous esophageal mucosa from injury by refluxed gastric juice. As is true for any valve, failure of the LES can occur in two completely opposite ways, which lead to two distinct clinical disease entities. Regardless of the type of LES failure, the secondary effects are produced proximally in the esophagus. Failure of the LES to relax or to open appropriately leads to the inability of the esophagus to propel food into the stomach, esophageal distention, and the condition known as achalasia. On the other hand, failure of the LES to remain closed leads to an increased exposure of the squamous epithelium to gastric juice and the condition known as GERD.

The LES has no anatomic landmarks and cannot be seen endoscopically; it is identified on manometry as a rise in pressure over gastric baseline pressure. This high-pressure zone is normally present except in two situations: (1) after a swallow, when it is momentarily dissipated or relaxes to allow passage of food into the stomach; and (2) during a belch, when it allows gas to be vented from a distended fundus. The common denominator for virtually all episodes of gastroesophageal reflux is the loss of this normal high-pressure zone or barrier. When the barrier is absent, resistance to the flow of gastric juice from an environment of higher pressure (the stomach) to an environment of lower pressure (the esophagus) is lost. In early GERD, this is usually caused by a transient loss of the barrier. In advanced GERD, there is usually a permanent loss of the barrier.¹¹

There are three characteristics of the LES or high-pressure zone that maintain its function as a barrier to intragastric and intra-abdominal pressure challenges. Two of these characteristics – the overall length and pressure of the LES – work together and depend on each other to provide resistance to the flow of gastric juice from the stomach into the esophagus.¹² The shorter the overall length, the higher the pressure must be for the LES to maintain sufficient resistance to remain competent (Fig. 42-13). Consequently, the effect of a normal LES pressure can be nullified by a short overall LES length, and the effect of a normal overall LES length can be nullified by a low LES pressure. A fundamental principle for surgeons to understand is that the length of the barrier or LES is critical to its function.

Figure 42-13. Relationship of the length and pressure of the lower esophageal sphincter in maintaining competence of the gastroesophageal barrier.

Foreshortening of LES length occurs naturally with gastric filling as the terminal esophagus is “taken up” by the expanding fundus (Fig. 42-14);¹³ this is similar to the shortening of the neck of a balloon as it is inflated. With excessive gastric distention (e.g., with overeating), the length of the LES shortens to a critical point at which it gives way, the pressure drops precipitously, and reflux occurs (Fig. 42-15).¹⁴ If the length of the LES is permanently shortened, then further shortening caused by the normal gastric distention with normal-volume meals results in postprandial reflux. In this situation, competency of the barrier is an ever-constant clinical problem. The observation that gastric distention results in shortening of the LES down to a critical length so that the pressure dissipates, the lumen opens, and reflux occurs provides a mechanical explanation for transient LES relaxations without invoking a neuromuscular reflex. If only the LES pressure and not its length is measured (e.g., with a Dent sleeve), the event appears as a spontaneous relaxation of LES pressure.¹⁵ In reality, it is the progressive shortening of the LES rather than the transient LES relaxations that results in the loss of LES pressure.

Variations in the anatomy of the cardia, from a normal acute angle of His to an abnormal dome architecture of a sliding hiatal hernia, influence the ease with which the sphincter is shortened by gastric distention. A hernia can result from the pulsion force of abdominal pressure on the esophageal hiatus or from the traction produced by inflammatory fibrosis of the esophageal body. The resulting alteration in the geometry of the cardia places the sphincter at a mechanical disadvantage in maintaining its length with progressive degrees of gastric distention. Greater gastric distention is necessary to open the barrier in patients with an intact angle of His than in those with a hiatal hernia.¹⁶ The reason is that the dome or funnel shape of a hiatal hernia allows the wall tension forces that pull open the barrier with gastric distention to be more effectively applied to the gastroesophageal junction,¹⁷ and it accounts for the common association of a hiatal hernia with GERD. Kahrilas et al.¹⁸ demonstrated this mechanical disadvantage by studying the effect of intragastric air infusion on the number of transient LES relaxations or “shortenings” per hour. Patients with hiatal hernias had significantly more transient LES relaxations per hour than did control subjects without hernias. The reduction in length became significant 20 to 30 minutes after the beginning of air infusion and occurred in a distal to cephalad direction before a loss of LES pressure was observed.

Figure 42-14. Effect of increasing gastric volume on the shortening of the lower esophageal sphincter length. As the stomach expands, the gastric body takes up the inferior aspect of the sphincter causing its length to shorten. (From Mason RJ, Lund RJ, DeMeester TR, et al. Nissen fundoplication prevents shortening of the sphincter during gastric distention. *Arch Surg* 1997;132:719–726, with permission.)

Figure 42-15. Representation of the loss of competence of the lower esophageal sphincter with shortening of its length. As a critical length is reached, there is a precipitous drop in sphincter pressure reflecting loss of competence. (From Pettersson GB, Bombeck CT, Nyhus LM. The lower esophageal sphincter: mechanisms of opening and closure. *Surgery* 1980;88:307–314, with permission.)

The third characteristic of the LES high-pressure zone is its position. A portion of the overall length of the high-pressure zone is normally exposed to the positive intra-abdominal pressure environment and is commonly referred to as the abdominal length of the LES.¹⁹ During periods of increased intra-abdominal pressure, the resistance of the LES would easily be overcome if its position were such that abdominal pressure was unable to be applied equally to the LES and the stomach.^{20–22} This is analogous to sucking on a soft soda straw immersed in a bottle of liquid; the positive hydrostatic pressure of the fluid and the negative pressure inside the straw from sucking cause the straw to collapse instead of allowing the liquid to flow up the straw in the direction of the negative pressure. When the abdominal length of the LES is inadequate, increases in intra-abdominal pressure will be applied to the stomach but not the LES thereby encouraging reflux to occur. Studies have shown that the critical length of abdominal LES is 1 cm, below which almost no LES pressure will be sufficient to maintain competency of the sphincter.¹⁵

In the fasting state deficits in LES pressure, overall length, or abdominal length will lead to an increased likelihood of sphincter incompetence. An LES defective in all three parameters is particularly likely to be associated with increased reflux of gastric juice into the esophagus. This reflux can result in inflammatory injury to the mucosa and ultimately to the muscularis propria of the esophageal body, thereby causing a reduced contraction amplitude of the esophageal body and interrupted or dropped peristaltic sequences. Continued reflux can lead to progressive loss of effective esophageal clearance, protracted esophageal exposure to the refluxed material and ultimately further organ injury (Fig. 42-16).^{23,24}

Causes and Consequences of the Failure of the Gastroesophageal Barrier

Early GERD is initiated by increased transient losses of the barrier as a result of gastric overdistention from excessive air and food ingestion.^{11,25} The tension vectors produced by gastric wall distention pull on the gastroesophageal junction, which results in the terminal esophagus being “taken up” into the stretched fundus, thereby reducing the length of the LES. With overeating, a critical length is reached (usually about 1 to 2 cm) at which the sphincter gives way; its pressure drops precipitously, and reflux occurs (Fig. 42-15). If the swallowed air is vented, gastric distention is reduced, the length of the LES is restored, and competency returns until subsequent distention again shortens it and further reflux occurs. Aerophagia is common in patients with GERD because they swallow their saliva more frequently to neutralize the acidic gastric juice that is refluxed into the esophagus.²⁶ Together, the actions of overeating and air swallowing result in the common complaint of postprandial bloating, repetitive belching, and heartburn in patients with early GERD. The high prevalence of the disease in the Western world is thought to be a result of the eating habits of Western society.²⁷ Gastric distention from overeating, along with delayed gastric emptying resulting from the increased ingestion of fatty foods, leads to prolonged periods of postprandial gastric distention with shortening of the LES and repetitive transient loss of the barrier. Surgical correction with a fundoplication prevents the shortening of the barrier with progressive degrees of gastric distention by diverting the forces that pull on the gastroesophageal junction.¹⁴

Figure 42-16. Overview of the progressive nature of GERD and the effect of the lower esophageal sphincter and esophageal body on reflux in the upright and supine positions.

In advanced GERD, permanent loss of sphincter length occurs from inflammatory injury that extends from the mucosa into the muscular layers of the LES. Fletcher et al.²⁸ showed that in the fasting state, there is a persistent region of high acidity in the area of the gastroesophageal junction and that this region of acidity migrates 2 cm proximally after meals.²⁹ This migration occurs from distention of the stomach with eating and pulling apart of the distal high-pressure zone or LES, thus allowing the area of high acidity to move proximal to the squamocolumnar junction. This proximal movement exposes the distal esophageal squamous mucosa to acid and results in the formation of cardiac mucosa. Cardiac mucosa is an acquired mucosa that replaces chronically injured squamous mucosa in the terminal esophagus.³⁰ The inflammatory process can extend into the muscular layer of the LES, thereby resulting in muscle cell injury with permanent shortening of the high-pressure zone or LES and a concomitant reduction in the amplitude of the high-pressure zone or barrier pressure.^{30–32} A defective barrier is recognized when the length or pressure of the LES measured during the fasting state is below the 2.5 percentile of normal.³³

For clinicians, the finding of a permanently defective LES has several implications. First, symptoms in patients with a defective LES can be difficult to manage, and mucosal damage may persist with medical therapy.³⁴ Surgery is usually required to achieve consistent long-term symptom relief in these patients to restore a gastroesophageal barrier and interrupt the natural history of the disease. It has been shown repeatedly that a laparoscopic Nissen fundoplication can consistently restore the length and pressure of the LES to normal parameters.³⁵ Newer techniques of sphincter augmentation such as with a magnetic bracelet is an alternative means of restoring the LES that is gaining in popularity.³⁶ Second, a permanently defective LES is commonly associated with reduced contractility and abnormal wave progression of the esophageal body.³⁷ For this reason, careful evaluation of the esophageal body is critical in the evaluation for antireflux surgery for potential tailoring of the operation with a partial fundoplication. Third, a permanently defective LES and the loss of effective esophageal clearance can lead to mucosal injury such as erosive esophagitis or Barrett metaplasia, repetitive regurgitation and aspiration events and ultimately pulmonary fibrosis. Without reestablishing a barrier, chronic use of acid suppression therapy may simply mask the symptoms due to modification of the pH; however, in the setting of a structurally defective LES, reflux will continue unabated.³⁸

EVALUATION OF ESOPHAGEAL FUNCTION

A thorough understanding of the patient's underlying anatomic and functional deficits is fundamental to the successful treatment of esophageal disease. The diagnostic tests that are employed to evaluate the esophagus are those used to visualize structural abnormalities, to detect functional abnormalities, and to measure esophageal exposure to gastric juice. At the authors' center a panel of four diagnostic tests are used routinely in the evaluation of known or suspected reflux disease: barium esophagram, upper endoscopy, high-resolution esophageal manometry, and ambulatory pH monitoring.

Radiographic Evaluation

Radiographic assessment of the anatomy and function of the esophagus and stomach is one of the most important aspects of the esophageal evaluation, provided the surgeon has a working knowledge of esophageal physiology. Classically, the barium esophagram has been described as a road map for the esophagus. The first diagnostic test in patients with suspected esophageal disease should be a barium swallow that includes a full assessment of the stomach and the duodenum.³⁹ Video recording of the study greatly aids in the evaluation by providing the surgeon with a real-time visualization of bolus transport and the size and reducibility of the hiatal hernia. The study also provides anatomic information, such as the presence of obstructing lesions and structural abnormalities of the foregut.

The pharynx and the UES are evaluated in the upright position, allowing assessment of the timing and coordination of the events of pharyngeal transit.⁴⁰ This includes oropharyngeal bolus transport, pharyngeal contraction, opening of the pharyngoesophageal segment, and degree of airway protection during swallowing. It readily identifies a diverticulum, stasis of the contrast medium in the valleculae, cricopharyngeal bar, or narrowing of the pharyngoesophageal segment. These are anatomic manifestations of neuromuscular disease and result from the loss of muscle compliance from the deinnervation of the skeletal muscle of the pharynx and the cervical esophagus.⁴¹

The assessment of bolus transport on video esophagography often adds to or complements the information obtained by esophageal manometry. Esophageal clearance is optimally assessed by

observing several individual swallows of barium with the patient in both the upright and supine positions; the study can be performed with both liquid and solid bolus material. During normal swallowing, a primary peristaltic wave is generated that completely strips the bolus out of the esophagus and into the stomach. Residual material rarely stimulates a secondary peristaltic wave; rather, an additional pharyngeal swallow is usually required.

The protocol developed and utilized at the authors' institution has previously been reported.⁴² Normal subjects in the prone position should be able to clear at least three of five 10-mL liquid barium boluses with one swallow and have only one episode of proximal escape or distal retention of a barium bolus with the five swallows. Normal subjects can also clear a solid barium bolus with four or fewer swallows in the upright position. Motility disorders with disorganized or simultaneous esophageal contraction give a segmented appearance to the barium column. This can often give a beading or corkscrew appearance to the barium within the esophagus. In patients with dysphagia, the use of a barium-impregnated marshmallow, piece of bread, or hamburger can identify an esophageal transport disturbance that is not evident on the liquid barium study. A 13-mm barium tablet is another useful adjunct that can be used to determine how well solid material can clear the esophagus, and identify areas of clinically significant narrowing since solid food dysphagia typically is present with luminal narrowing below 13 mm.

A hiatal hernia is present in a high percentage of patients with gastroesophageal reflux.⁴³ These are best demonstrated with the patient in the prone position; the increased intra-abdominal pressure produced in this position promotes displacement of the hernia above the diaphragm. The hiatal hernia is an important component of the underlying pathophysiology of reflux. A large (>5 cm) or irreducible hiatal hernia may be associated with chronic reflux and esophageal foreshortening. The diagnosis of reflux disease is not accurately made on video esophagram. Spontaneous reflux to the level of the thoracic inlet seems to correlate with a positive pH test, but evoked reflux and spontaneous reflux into the distal esophagus are not. Moreover, failure to observe reflux during a video esophagram does not indicate the absence of disease.

A full-column technique with distention of the esophageal wall can discern extrinsic compression of the esophagus, and a fully distended esophagogastric region is necessary to identify narrowing from a Schatzki ring, stricture, or obstructing lesion. Mucosal relief or double-contrast films can be obtained to enhance the detection of small neoplasms, esophagitis, and varices. Assessment of the stomach and duodenum during the barium study is helpful for the evaluation of the patient with esophageal symptoms (ESs). A gastric or duodenal ulcer, a neoplasm, or poor gastroduodenal transit can mimic many of the symptoms that are suggestive of an esophageal disorder.

Endoscopic Examination

Endoscopic evaluation of the esophagus is essentially the physical examination of the foregut. It is a critical part of the assessment of a patient with esophageal disease and is indicated in essentially every patient who is being evaluated for GERD. A barium study obtained before esophagoscopy is helpful to the endoscopist by directing attention to locations of subtle change and alerting the examiner to such potential danger spots as a cervical vertebral osteophyte, an esophageal diverticulum, a deeply penetrating ulcer, or a carcinoma. Regardless of the radiologist's interpretation of an abnormal finding, each structural abnormality of the esophagus should be examined visually with an endoscope.

During every endoscopic examination, the locations of three specific landmarks are routinely obtained relative to the front incisors: the squamocolumnar junction, gastroesophageal junction, and the diaphragmatic crura. The crura are usually evident by having the patient sniff. The gastroesophageal junction is the location at which the gastric rugal folds meet the tubular esophagus; it is normally aligned with the squamocolumnar junction. The squamocolumnar junction is the location at which the velvet and darker rose-colored columnar epithelium changes to the lighter squamous epithelium. When this junction is not clear, narrow band imaging (NBI), a feature that is standard on all modern endoscopic systems, is extremely helpful in distinguishing columnar from squamous mucosa. Particular effort should be made to detect any tongues, islands, or a circumferential segment of columnar-lined esophagus (CLE) in the distal esophagus.

When erosive esophagitis is found, an objective grading system should be utilized to communicate the severity of the findings. Currently, the Los Angeles classification is the most commonly utilized system.⁴⁴ Grade A is defined as one or more mucosal break ≤ 5 mm that does not extend between the tops of mucosal folds. Grade B is defined as one or more mucosal break > 5 mm that does not extend between the tops of the mucosal folds. Grade C is defined as one or more mucosal break that is

continuous between the tops of two or more mucosal folds but involves <75% of the circumference. Grade D is defined as one or more mucosal break that involves $\geq 75\%$ of the circumference.

Barrett esophagus is a pathologic condition in which the tubular esophagus is lined with columnar epithelium as opposed to the normal squamous epithelium. It is suspected at endoscopy when there has been separation of the squamocolumnar junction from the gastroesophageal junction. When columnar metaplasia is observed, it must be biopsied to confirm the presence of intestinal metaplasia in order to make the diagnosis of Barrett esophagus; the finding of cardiac metaplasia without goblet cells does not meet this criteria in the United States. On histologic examination, it appears as columnar mucosa with goblet cells and is called intestinal metaplasia. Early metaplasia is often manifest as an irregular or eccentric squamocolumnar junction. Routine four-quadrant biopsies with jumbo forceps are necessary every 2 cm of columnar metaplasia. In addition, the likelihood of identifying goblet cells is greatest at the cephalad portion of a columnar segment, especially at the squamocolumnar junction.⁴⁵ Barrett esophagus is susceptible to ulceration, bleeding, stricture formation, and malignant degeneration. The earliest histologic sign of malignant degeneration is high-grade dysplasia (HGD) or intramucosal adenocarcinoma. These dysplastic changes have a patchy distribution, so a minimum of four biopsy specimens every 2 cm should be taken from the Barrett mucosa-lined portion of the esophagus. A study of intramucosal adenocarcinomas arising in Barrett esophagus showed that most of the tumors arose in the distal Barrett segment, closer to the stomach.⁴⁶

Abnormalities of the cardia or gastroesophageal junction can be visualized by retroflexion of the endoscope and provide a complementary assessment regarding the competency of the gastroesophageal barrier. Hill et al. have graded the appearance of the gastroesophageal valve from I to IV according to the degree of unfolding or deterioration of the normal architecture (Fig. 42-17).⁴⁷ This commonly used grading system has allowed endoscopists to maintain uniformity in their reporting. The Hill grade correlates well with the competence of the gastroesophageal barrier, with increasing acid exposure prevalent in patients with worsening Hill grade.

A hiatal hernia is diagnosed by observing separation of the gastroesophageal junction from the crura. By definition, a hiatal hernia is present when at least 2 cm of the top of the rugal folds has migrated above the pinch of the diaphragmatic crura. A prominent sliding hiatal hernia is frequently associated with GERD. When a hernia is observed, particular care is taken to exclude Cameron ulcers or gastritis within the herniated stomach.

As the endoscope is slowly withdrawn, the esophagus is again examined, and biopsy samples are taken. The location of the cricopharyngeus is identified, and the larynx and vocal cords are visualized. Acid reflux may result in inflammation of the larynx. Vocal cord movement should also be recorded, both as a reference for subsequent surgery and as an assessment of the patient's ability to protect the airway.

Esophageal Manometry

Fundamental to the evaluation of a patient with benign esophageal disease is the assessment of esophageal contractility, coordination, and sphincter function. Manometry is indicated whenever an abnormality of the esophagus is suggested by the symptoms of dysphagia, odynophagia, chest pain, heartburn, and regurgitation. It is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders, such as achalasia, diffuse esophageal spasm, nutcracker esophagus, or hypertensive LES. It can also identify ineffective esophageal body motility as a result of GERD or systemic diseases such as scleroderma, dermatomyositis, polymyositis, or mixed connective tissue disorders. In patients with symptomatic GERD, esophageal manometry can identify a mechanically defective LES and evaluate the adequacy of the esophageal body contraction amplitudes and waveform. Finally, manometry is mandatory for accurate placement of an ambulatory pH monitor in relationship to the upper border of the LES.

High-resolution manometry (HRM) has now become standard technology over the past several years and represents an improvement in methodology that leads to a more detailed data collection and simpler data interpretation, especially with regard to the esophageal body. The concept behind this technology is that by vastly increasing the number of sensors and reducing the space between the sensors, it can provide representation of the entire pressure profile along the esophagus from the pharynx to the proximal stomach without the need to reposition or to pull back the catheter as in conventional manometry.

The most commonly used HRM system is a solid-state manometric assembly with 36 circumferential sensors spaced at 1-cm intervals and are available from different manufacturers. These transducers

detect the pressure over a length of 25 mm in each of 12 radially dispersed sectors. The recorded pressure at each sector is then averaged, making each of the 36 sensors a circumferential pressure detector with the extended frequency response characteristic of solid-state manometric systems and free of the hydrostatic influence characteristic of water-perfused systems. The increased number of circumferential pressure sensors results in a vastly greater amount of data and detail. Interpretation of the data has been simplified by a sophisticated topographic plotting algorithm that converts the traditional linear waveform tracings into an esophageal pressure topography or Clouse plot (Fig. 42-18). Sphincter characteristics and esophageal motor function are represented by isocontour manometric plots, eliminating the need for the tedious analysis of the increased waveform data that are generated by the 36 sensors.

Figure 42-17. Endoscopic grading of the gastroesophageal junction during the retroflex view. (From Oberg S, Peters JH, DeMeester TR, et al. Endoscopic grading of the gastroesophageal valve in patients with symptoms of gastroesophageal reflux disease (GERD). *Surg Endoscopy* 1999;13(12):1184–1188, with permission.)

Figure 42-18. High-resolution manometry with line tracings and converted pressure topography or Clouse plot view. (From Pandolfino JE, Roman S. High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thor Surg Clin* 2011;21:465–475, with permission.)

The manometry procedure is performed by passing the catheter into the stomach and esophagus to measure contraction pressures and waveform in the esophageal body and the sphincters' resting pressure and response to swallowing. The lubricated catheter is passed through the nostril and into the esophagus. The catheter is advanced until a portion of the sensors are in the stomach. In patients who have a dilated or tortuous esophagus such as suspected achalasia or a large PEH, it is recommended that the catheter be passed endoscopically to ensure that it is properly positioned into the stomach and not coiled in the esophagus. The pressure topogram is assessed to ensure that the catheter is completely traversing the UES and the LES. Unlike with traditional manometry, a HRM study can be performed with 10 swallows without the need to repeatedly move the catheter back and forth for different portions of the examination. The patient is then asked to refrain from swallowing for 30 seconds with quiet breathing, which allows the capture of a landmark frame for assessment of the resting UES and LES. The patient is positioned supine with the head elevated and is asked to swallow 5 mL aliquots of water separated by a minimum of 30 seconds to prevent deglutitive inhibition. A complete manometric study includes the assessment of the structural characteristics of the LES, the degree of LES relaxation, the esophageal body coordination, contraction amplitude and waveform, and the UES function.

Lower Esophageal Sphincter

The resting LES is assessed during the landmark frame (Fig. 42-19). The lower (distal) border of the LES is the point at which the resting pressure rises above the gastric baseline; the upper border is the point at which sphincter pressure reaches the esophageal baseline. The respiratory inversion point is identified when the positive excursions that occur with breathing in the abdominal environment change to negative deflections in the thoracic environment. The respiratory inversion point is the functional division between the abdomen and thorax. The resting pressure of the LES is the pressure above gastric baseline measured during midrespiration at the respiratory inversion point. The overall length of the sphincter is the distance from the distal border to the proximal border. The abdominal length is the distance from the distal border to the respiratory inversion point and represents the portion of the LES that is subject to fluctuations in intra-abdominal pressure. The measurements for each of these components from each transducer are expressed as an average during the landmark frame, which extends for 30 seconds.

Figure 42-19. High-resolution esophageal manometry showing the landmark frame. The upper and lower esophageal sphincters are observed at the top and bottom of the frame, respectively. Resting pressure and length measurements of the sphincters can be determined in this portion of the study while the patient is refraining from any swallowing. (From Pandolfino JE, Roman S. High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thor Surg Clin* 2011;21:465–475, with permission.)

A structurally defective sphincter is identified by one that has low resting pressure or short length. Based on conventional manometry in normal volunteers, the following characteristics have traditionally been used to identify a structurally defective LES: (1) an average LES pressure of less than 6 mm Hg, (2) an average abdominal length of less than 1 cm, and (3) an average overall length of less than 2 cm.

Based on normative data, these values are below the 2.5 percentile. A defect in one or even two components of the LES may be compensated by good esophageal body function, but when all three components are defective, excessive esophageal acid exposure is inevitable. With the HRM technique, normal overall LES length should be 2.7 to 4.8 cm and mean basal resting pressure of the LES should be 13 to 43 mm Hg.

It should be noted that while HRM has revolutionized the assessment of the esophageal body due to improved resolution of contraction waves, the assessment of the LES has been less optimal. This is primarily due to the nature of the HRM catheter, which functions as a sleeve manometry catheter and results in circumferential averaging of pressure data. For this reason, length assessment of the LES and UES is believed to be less detailed than that obtained with conventional manometry with a manually pulled through catheter.⁴⁸ It is believed that the newly developed 3D HRM catheter will allow more precise or detailed evaluation of the LES structure, but clinical experience is necessary to fully evaluate its additive value.

Lower Esophageal Sphincter Relaxation

The LES pressure normally drops to gastric baseline immediately after initiation of a swallow, and remains open until the oncoming peristaltic wave reaches the stomach (Fig. 42-18). A characteristic postrelaxation contraction of the LES is subsequently observed as the LES closes with passage of the bolus. Using HRM, relaxation is assessed during a 4-second segment of the time between initiation of the swallow and when the peristaltic wave reaches the LES. This 4-second window is often captured in a noncontiguous manner during the swallow to eliminate the effect of respiratory variation from the crura and is termed the integrated relaxation pressure (IRP). An IRP >15 mm Hg is considered elevated and may result in clinically significant outflow resistance through the LES.

Esophageal Body Motility

The esophageal body is evaluated by assessing contraction amplitude, duration, slope, velocity, and morphology (i.e., single, double, or triple peaked). A physiologic gap in contraction or proximal peristaltic break typically occurs in the upper one-third of the esophagus, and corresponds to the transition zone between the striated muscle above and smooth muscle below. Pathologic breaks are those that are >2 cm long or if a break occurs in the distal esophagus. HRM has had its greatest improvement in the assessment of esophageal body function. It is important to allow 30 seconds between swallows to prevent deglutitive inhibition of the body, a physiologic dampening or absence of peristalsis with repetitive swallowing.

Figure 42-20. High-resolution esophageal manometry during a swallow. The initiation of swallowing is reflected by transient relaxation of the UES followed by a peristaltic pressure wave progressing down the esophageal body. Note the LES relaxes at the initiation of swallowing. A characteristic peristaltic break is observed in the upper third of the esophageal body at the transition zone between the striated and smooth muscle. (From Pandolfino JE, Roman S. High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thor Surg Clin* 2011;21:465–475, with permission.)

Further improvement in assessing esophageal body function with HRM has been the use of the distal contractile integral (DCI) which gives a global assessment of esophageal contractile function. This is an integrated summation of the contractile pressures generated between the proximal peristaltic break and the upper border of the LES and is calculated as the product of amplitude (mm Hg) × duration (seconds) × length (cm), with normal values ranging from 500 to 4,300 (Fig. 42-20). Based on

conventional manometry, it was believed that a minimum of distal contraction amplitude of >20 mm Hg 5 cm above the LES was necessary to overcome the resistance of an antireflux procedure. With HRM it is currently believed that a DCI >500 mm Hg*sec*cm is necessary to minimize the possibility of postoperative dysphagia; however, clinical validation of this cutoff has not been performed.

Upper Esophageal Sphincter

The position, length, and resting pressure of the UES and its relaxation with swallowing are assessed with a technique similar to that used for the LES. The key features to be assessed are the adequacy of pharyngeal contraction and the timing and extent of UES relaxation. An indirect measure of UES stiffness or loss of compliance is the intrabolus pressure, which appears as a pressure rise or shoulder on the upstroke of the pharyngeal contraction.

High-Resolution Impedance

Even with the addition of high-resolution topography, manometric data often does not correlate with the effective passage of the swallowed bolus. To overcome this shortcoming, the barium video esophagram has been used to complement manometry; however, one drawback is that these tests cannot be performed simultaneously. Not infrequently, a discrepancy may exist between these studies with a normal video esophagram but poor esophageal body manometry characteristics, or vice versa. Currently, the authors are utilizing combined HRM with high-resolution impedance to gain additional information on bolus transport.

Ambulatory pH Monitoring

The development of ambulatory pH monitoring by DeMeester and Johnson⁴⁹ was a major advance in the unraveling of the pathophysiology of GERD. All previous tests had relied on the identification of reflux by a provocative maneuver, which had little relevance to the patient's daily activities. The 24-hour pH monitoring test allowed objective assessment of esophageal exposure to gastric juice in a patient in a continuous setting. It is considered the gold standard for the diagnosis of GERD because it has the highest sensitivity and specificity of all tests currently available. It is indicated in any patient with symptoms suggestive of GERD, unless the symptoms are trivial or permanently abolished by a short course of acid suppression therapy. The need for continued acid suppression should stimulate objective study. A 24-hour pH monitoring study is especially important in patients who are being considered for antireflux surgery. Atypical presentations of GERD are also a common indication; they include such symptoms as noncardiac chest pain (i.e., pain despite a normal cardiac evaluation) and respiratory symptoms (RSs) such as shortness of breath, cough, nocturnal wheezing, and chronic hoarseness. In such patients, 24-hour pH monitoring allows confirmation of the diagnosis of GERD and can relate the occurrence of the symptoms to an episode of reflux.

To perform the standard pH test, a thin catheter containing a pH electrode is passed transnasally into the esophagus and placed 5 cm above the upper border of the LES, a position that has been previously determined by manometry. Different probes are available, but bipolar glass electrodes are preferred for their greater reliability and their elimination of the need for an external reference electrode. The electrode is connected to an external portable digital storage device that is kept at the patient's side, and pH values are continuously recorded at 6-second intervals for 24 hours (i.e., a complete circadian cycle). Precalibration and postcalibration of the system to pH levels of 1 and 7 is important to exclude electrode drift. A gastric "dipstick" maneuver is performed prior to securing the location of the catheter to confirm acid in the stomach and that the patient does not have atrophic gastritis. The patient is then instructed to carry out normal daily activities but to avoid strenuous exertion. He or she is asked to remain in the upright position while awake during the day, lying down supine only at night while sleeping, and to ingest two meals at the usual time. The diet is standardized only by its absence of food and beverages with a pH value of less than 5.0 and greater than 6.0. The patient notes in a diary the times of meals, retiring for sleep, and rising the following morning as well as the presence and duration of any symptoms. At the authors' institution, patients are also asked to consume a challenge meal consisting of a hamburger, French fries, and a milk shake. It has been found that a refluxogenic meal can often uncover early acid reflux disease that would not ordinarily be detected during a typical 24-hour period.⁵⁰ Figure 42-21 shows typical 24-hour pH tracings from a healthy subject and from a patient with GERD. Medications such as H₂ blockers and prokinetics should be discontinued for 48 hours before the testing begins. Proton pump inhibitors (PPIs) (e.g., omeprazole) should be stopped for 2 weeks before pH monitoring because of their long-lasting action.

It is important to emphasize that 24-hour esophageal pH monitoring should not be considered a test for reflux; rather, it is a measurement of the esophageal exposure to gastric juice. The measurement is expressed as the percentage of time that the esophageal pH was below 4 during the 24-hour period. Just measuring the percentage of time that the pH is less than 4, although concise, does not reflect how the exposure has occurred; for example, it may have occurred in a few long or several short reflux episodes. Consequently, two other assessments are necessary: (1) the frequency of the reflux episodes and (2) their duration. For this reason, esophageal exposure to gastric juice is best assessed by the following measurements:

Figure 42-21. Dual-probe 24-hour pH tracing of patient. The top tracing is of the pH sensor located below the upper esophageal sphincter and the bottom tracing is of the pH sensor located 5 cm above the top of the lower esophageal sphincter. Episodes of pH < 4 are considered acid events. In this example the patient has abnormal acid exposure in the distal esophagus with several reflux events extending into the proximal esophagus.

- The cumulative time that the esophageal pH is below 4 expressed as the percentage of the total, upright, and supine monitored times;
- The frequency of reflux episodes, when the pH drops below 4, expressed as the number of episodes per 24 hours;
- The number of episodes during which the pH remained below 4 for longer than 5 minutes per 24 hours; and
- The time in minutes of the longest recorded reflux episode, the longest time the pH consistently remained below 4.

Normal values for these six components of the 24-hour record were derived from 50 asymptomatic control subjects. The upper limits of normal were established at the 95th percentile.⁵¹ If the values of symptomatic patients are outside of the 95th percentile of normal subjects, they are considered to be abnormal for the component measured. There is a uniformity of normal values for these six components as reported by centers throughout the world. The normal values for the six components obtained from 50 healthy volunteers are shown in [Table 42-1](#). A composite scoring system was developed by DeMeester and Johnson that integrates the different components of the pH record into a single measurement of esophageal acid exposure. This composite score is calculated from the six parameters with use of their standard deviations as weighing factors.⁵¹

Advances in technology have made pH testing more comfortable for the patient with the development of a catheter-free miniaturized pH electrode. The Bravo system (Medtronic, Minneapolis, MN) allows the transnasal or transoral deployment of a small capsule that attaches to the esophageal mucosa and transmitting pH data by radiotelemetry to a pager-sized receiver, thus eliminating the need for an unpleasant transnasal catheter. It may also provide a more accurate physiologic picture by allowing patients to perform their normal daily activities without the social and behavioral restrictions imposed by the catheter. Another major advantage of the Bravo capsule is the ability to record for prolonged periods, and routine monitoring of 48 hours is now performed with improved diagnostic capabilities.⁵² New normal thresholds have been defined and validated for the 48-hour Bravo pH test, with the normal composite score for the first 24 hours being 14.0, the second 24 hours being 14.0, and the combined 48-

hour score being 16.0.⁵¹

Table 42-1 Normal Manometric Values of the Distal Esophageal Sphincter in 50 Subjects

Median Parameter	Value	2.5th Percentile	97.5th Percentile
Pressure (mm Hg)	13	5.8	27.7
Overall length (cm)	3.6	2.1	5.6
Abdominal length (cm)	2	0.9	4.7

In patients with symptoms of chronic cough, hoarseness, or pulmonary aspiration, placement of an additional pH electrode in the proximal part of the esophagus or pharynx can be helpful.⁵³ Such dual-probe catheters are particularly helpful in determining if gastroesophageal reflux events extend proximally, which could give indirect evidence of acid exposure into pharyngeal area and subsequent irritation. If the accumulated acid exposure in the proximal esophagus is greater than 1% or the number of reflux episodes is more than 24 (particularly if there is a temporal relationship between the reflux episodes and the onset of the symptoms), reflux can be documented and assumed to be the cause of the patient’s RSs.⁵³ A composite score has been developed for proximal pH monitoring, analogous to that developed for the distal probe, with the normal threshold composite score being 16.4.⁵²

Additional testing is sometimes necessary if the standard methods of assessing esophageal function fail to yield conclusive results, particularly when investigating the relationship of acid reflux and extraesophageal symptoms. A novel pharyngeal pH system has been developed that allows a pH probe to be positioned directly into the pharynx just below the uvula (Restech pH probe, Respiratory Technology Corp, San Diego, CA, USA).⁵³ This probe utilizes a novel antimony sensor that allows measurement of pH within the humidified air of that environment without drying out and creating artifacts. Early clinical experience with this technique indicates that it is a useful adjunct diagnostic test in patients suspected of having laryngopharyngeal reflux (LPR).

Testing for reflux that is nonacidic or weakly acidic can be gained by multichannel intraluminal esophageal impedance monitoring. This type of measurement determines the resistance to the flow of current through a given medium (impedance). The impedance to current changes as the composition of the medium in which the current is traveling changes (i.e., air, liquids, or solids). Coupled with a pH probe, it can differentiate acid reflux from nonacid reflux, which may be particularly useful in patients who remain symptomatic on acid suppression therapy.

Lastly, the assessment of gastric function can be important in many patients with ESs. Disorders of gastric emptying frequently can contribute to or be confused with esophageal disease, especially GERD. Nuclear medicine radioisotope with solid food matter such as scrambled eggs has been utilized for this purpose, and is indicated in any patient being evaluated for GERD who also has a history of nausea, early satiety, and vomiting. Such information may be invaluable to prevent performing an antireflux operation in the setting of gastroparesis. The most reliable results are obtained with the use of a 4-hour study rather than one that just determines a half-time of emptying.

CONCLUSIONS

Although seemingly simple, the anatomy and physiology of the esophagus is complex. Understanding the anatomic relationships is critical to enable safe surgery on the esophagus. Functional studies allow identification of abnormalities in the upper or lower esophageal sphincter as well as the esophageal body, and pH testing can determine the presence of increased exposure of the esophagus to refluxed gastric juice. An understanding of the relevant pathophysiology is critical to allow functional restoration of LES competence in patients with reflux disease, or to reduce the LES outflow resistance in patients with achalasia. While complex, restoration of esophageal function can bring tremendous improvements in quality of life and social satisfaction for patients, and is gratifying for esophageal surgeons.

GASTROESOPHAGEAL REFLUX DISEASE

Definition and Epidemiology

GERD is a very common disease, but developing an accurate definition of GERD is surprisingly difficult. In 2004, a group of experts came together in Montreal and concluded that GERD can be best defined as “a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications.”⁵⁴ Population-based studies have reported that one-third of Western populations experience the symptoms of GERD at least once a month, with 4% to 7% of the population experiencing daily symptoms.^{55,56} Its prevalence varies considerably around the globe and is highest in North America, Australia, and Western Europe and lowest in Africa and Asia.⁵⁷ It is also likely that both the prevalence and severity of GERD are increasing in many parts of the world. Time trend analyses have shown that the prevalence of GERD symptoms has increased progressively in most longitudinal studies, including those from the United States, Singapore, and China (Fig. 42-22).⁵⁸ Further, recent data reported by the Agency for Healthcare Research and Quality (AHRQ) indicate a marked increase (103%) in hospitalizations for treating disorders caused by GERD; a 216% increase in hospitalization of patients who, in addition to the ailment for which they were admitted, have milder forms of GERD; and a 39% increase in admission for GERD with severe symptoms including anemia, weight loss, and vomiting.⁵⁹ These data suggest that the current therapeutic approach to GERD may be inadequate.

Figure 42-22. Time trends for the prevalence of weekly heartburn from 1980 to 2005. (Reproduced with permission from El-Serag H. Time trends of gastroesophageal reflux disease: a systematic review. *Clin Gastroenterol Hepatol* 2007;5:17–26.)

Most patients with mild symptoms self-medicate with over-the-counter antacids or antisecretory agents, whereas those with more severe and persistent symptoms seek out medical attention. In contrast to duodenal ulcer disease, where the prevalence has markedly decreased, the prevalence and severity of GERD seem to be increasing (Fig. 42-23).⁶⁰ The diagnosis of a CLE is also increasing at a rapid rate, and deaths from end-stage benign esophageal disease are on an upward trend.⁶¹ These changes have occurred despite dramatic improvements in the efficacy of treatment options.

Two epidemiologic trends may be contributing to the increasing prevalence and severity of GERD over the past several decades. Population-based studies have shown that GERD is positively associated with obesity and negatively associated with gastric colonization with *Helicobacter pylori*. Over the past 20 to 30 years, the former has increased and the latter has decreased markedly in most Western countries. The relationship between GERD and body mass index (BMI) has been evaluated in a number of well-designed clinical studies. The frequency, duration, and severity of reflux symptoms were studied in 10,500 women of the Nurses' Health Study and a dose-dependent relationship between increasing BMI frequency of GERD symptoms was identified.⁶² Compared to normal-weight women (BMI 20 to 22.4), underweight women (BMI <20) were one-third less likely and overweight women (BMI 25 to 27.4) two times more likely to have frequent GERD symptoms. Obese women (BMI >30) had a nearly three times higher risk of frequent GERD symptoms. Recent meta-analyses confirm these findings, with studies from the United States demonstrating an association between increasing BMI and the presence of GERD.⁶³ High-resolution motility studies have shown a significant correlation with BMI and both intragastric pressure and gastroesophageal pressure gradients, providing a physiologic explanation for the BMI–GERD association.⁶⁴ These studies suggest that obese subjects are more likely to have esophagogastric junction disruption and abnormal pressure gradients favoring the development of reflux. Finally, the risk of Barrett esophagus has been correlated with the presence of central obesity. Measures of central obesity, including waist circumference and waist-to-hip ratios, were associated with both short- and long-segment Barrett esophagus, with a 4.1 higher odds ratio of long-segment Barrett in patients with a high waist-to-hip ratio.⁶⁵

Figure 42-23. Trends in hospitalization for duodenal ulcer and gastroesophageal reflux disease from the 1970s to 1990s in U.S. veterans. (Reproduced with permission from El-Serag HB, Sonnenberg A. Opposing time trends of peptic ulcer and reflux disease. *Gut* 1998;43:327–333.)

The possible pathogenic role of helical-shaped bacteria found in gastric fluids was first suggested in the late 19th century by the Polish scientist Walery Jaworski of the University of Krakow.⁶⁶ It was the publication of two Australian scientists in 1983 that convincingly demonstrated the pathogenic role of *H. pylori*.⁶⁷ These pioneering studies of Barry Marshall and Robin Warren from Perth, Australia, included self-experiments and were later awarded the Nobel Prize. *H. pylori* induces a significant inflammatory and immune response in the affected host, resulting in persistent inflammation in virtually all infected subjects.
